1,1,2,2-Tetracyanocyclopropane (TCCP) as supramolecular synthon†

Antonio Bauzá, Antonio Frontera* and Tiddo J. Mooibroek*

The 1,1,2,2-tetracyanocyclopropane (TCCP) unit presents a synthetically accessible and versatile synthon that can interact with lone-pair or π-electrons by 'non-covalent carbon bonding'. Complexes of TCCP with common small molecules, anions, aromatics like fullerences, amino acids and nucleobases were computed at the DFT BP86-D3/def2-TZVP level of theory. Binding energies vary between about −10 kcal mol⁻¹ for neutral guests and −15 to −50 kcal mol⁻¹ for anionic species. This is comparable to strong and very strong hydrogen bonding respectively. Thus, in addition to synthons that contain polarized hydrogen or halogen atoms, TCCP presents a new supramolecular synthon that awaits experimental exploitation.

Introduction

Living matter is for a great part governed by intermolecular recognition phenomena such as substrate/inhibitor/protein binding,1–4 signalling events5–8 and cell–cell interactions.9–11 Intra-molecular phenomena such as the folding of proteins12–14 or DNA/RNA15–18 are governed by the same physical forces. The design and synthesis of molecules that can influence such processes are the basis of many inquiries in supramolecular chemistry,19–23 and pharmacology.28–30 Underpinning these entities lack a convenient chemical anchor point. Thus, TCCP provides a rather unique case of a synthetically accessible and versatile supramolecular synthon that awaits experimental exploitation.

A major obstacle of their exploitation, however, is the synthetic accessibility of identified supramolecular synthons. In particular, the problem is how to incorporate a given synthon in a larger molecular framework. For example, the sulphur atom in SO₂ and SO₃ can participate in Chalcogen bonding interactions,36 but these entities lack a convenient chemical anchor point.

We have recently highlighted that sp³ hybridized carbon – the most abundant tetrel atom in living matter – can be a supramolecular synthon.47,48 More specifically, the 1,1,2,2-tetracyanocyclopropane (TCCP) motif (Scheme 1) was identified as an electron poor bowl, apt to accommodate an electron rich guest.47 Two convenient (high yielding) synthetic routes towards this motif are shown in Scheme 1: reaction of a primary or secondary alkyl halide with tetracyanoethylene (top);57–60 and reaction of an aldehyde or ketone with malonitrile (bottom).61,62 In both instances, numerous variations of the R-bearing moieties are readily available and provide a convenient way to obtain a practically infinite amount of TCCP derivatives. Thus, TCCP provides a rather unique case of a synthetically versatile and accessible supramolecular synthon that awaits utilization by the molecular scientists.

Scheme 1 Synthetic routes to 1,1,2,2-tetracyanocyclopropane (TCCP) structures. The molecular electrostatic potential map of 3,3'-dimethyl-TCCP was computed at the DFT-B3LYP-6-31G* level of theory and the color code spans from –130 (red) to +150 (blue) kcal mol⁻¹.63

Anticipating the experimental exploitation of TCCP, we here report on a comprehensive theoretical investigation of the binding interactions of a model for TCCP derivatives (where $R_1 = R_2 = H$) with three classes of compounds: commonly encountered small (neutral) molecules, common anions, and several aromatic systems including Nature’s aromatic building blocks.

**Results**

For our enquiries we conducted computations based on density functional theory (DFT) at the BP86-D3/def2-TZVP level of theory and Table 1 summarized the results of the interaction of TCCP with common small molecules. For several of these molecule pairs, *ab initio* calculations at the MP2/def2-TZVP level of theory were also conducted (denoted ‘a’ in Table 1) to validate our use of the more economical DFT approach. The comparative results are given in the ESI† (Table S1) and are in excellent agreement: computed distances differ less than 3% and computed energies typically less than 10%. In all cases, the minimized complex was subjected to an ‘atoms in molecules’ (AIM) analysis in order to identify atoms engaging in bonding contacts. Graphical renderings of these analyses are depicted in Fig. S1 (ESI†), and Fig. 1 shows representative examples for some complexes with small neutral molecules.

The complexation energy with the control guest methane ($-2.3$ kcal mol$^{-1}$) is very small and methane actually is not located in the electron poor binding pocket of TCCP (see Fig. S1, ESI†). All other guests do engage in tetrel bonding with the C3(ψ-CN) π-pot, although in several structures additional hydrogen bonding with TCCP’s N-atom(s) is also observed (i.e. in 4–6, 8, 10, 11, 20). These additional forces might explain the increased stability of these complexes over other, very similar ones. For example, the [H$_2$O···TCCP] pair 3 has an energy of about $-8.45$ kcal mol$^{-1}$, solely due to O···C tetrel bonding interactions, while the additional hydrogen bonds with dimethyl ether (4), 1,4-dioxane (5) and THF (6) result in energies of about $-11$ kcal mol$^{-1}$. The energies of other small molecules with O-donors (7–16) are very similar, between about $-7$ and $-10$ kcal mol$^{-1}$. The strongest of these that do not have additional H-bonding according to AIM are trimethylphosphaneoxide (14) ($-14.0$ kcal mol$^{-1}$) and dimethylsulfoxide (16) ($-12.2$ kcal mol$^{-1}$). This is in line with the increased polarization of O in these molecules.

Other small molecules considered where an atom other than oxygen functions as electron donor (17–28) gave very similar energies, ranging between about $-5$ to about $-10$ kcal mol$^{-1}$. Carbon monoxide (17) and dinitrogen (18) displayed the lowest predicted energies at about $-3$ kcal mol$^{-1}$.

Interestingly, the series with H$_2$O (3; $-8.5$ kcal mol$^{-1}$, 2.82 Å) H$_2$S (23; $-4.5$ kcal mol$^{-1}$, 3.40 Å), H$_2$N (19; $-9.4$ kcal mol$^{-1}$, 3.00 Å) and H$_2$P (25; $-4.9$ kcal mol$^{-1}$, 3.57 Å) suggest that TCCP prefers ‘hard’ over ‘soft’ donor atoms, while the trend might also result from the longer distance required by the ‘soft’ second-row donors.

All anionic guests appears to sit comfortably within the electron poor bowl shape of TCCP, and are held in place solely stabilizing interactions. The strongest of these is provided by $-11.1$ kcal mol$^{-1}$ for the triethylamine (10) complex, which is due to the additional hydrogen bonding with dimethyl ether (4), 1,4-dioxane (5) and THF (6) (see Table 1).

by one or multiple Tetrel bonding interactions, as evidenced by the AIM analyses (see Fig. 2 for representative examples, but also Fig. S1, ESI†). The interacting energies are summarized in Table 2, and range typically from −19.4 kcal mol⁻¹ for SCN⁻ (43) to −32.8 kcal mol⁻¹ for acetate (32). The two complexes with the largest energies (37 and 38) concern dianions (SO₂⁻ = −68.9 kcal mol⁻¹; SO₃⁻ = −88.1 kcal mol⁻¹). The latter (38) might well have some covalent character; the C–C N angles (143°) deviate significantly from the ~170–180° observed in the monoanionic complexes. The C–C N angles in 37 are about 164°, indicating that there is much less covalent character.

</table>

From the series with hydroxide 29 (−57.7 kcal mol⁻¹) > formate 30 (−58.7 kcal mol⁻¹) > acetate 31 (−30 kcal mol⁻¹) > perchlorate 33 (−18.6 kcal mol⁻¹) it seems evident that the interacting energies decrease when the negative charge becomes more spread out over a larger anion (although the hydride result (39) breaks this trend, likely due to the short distance). The anions where a N-donor atom formally bears the negative charge (40–43) bind weaker (about −20–25 kcal mol⁻¹) than the small anions with O-donor atoms (e.g. formate 30 with −31.8 kcal mol⁻¹). In the series with halogen donor atoms (44–49) there is a clear trend with energies ranging from −52.1 kcal mol⁻¹ for F⁻ (44) to −14.8 kcal mol⁻¹ for PF₆⁻ (49).

In general the interaction energies reported in Tables 1 and 2 are in good agreement with the MEP values of the guest molecules on their negative regions. For instance in the neutral O/N Lewis bases the MEP values vary from −58 kcal mol⁻¹ [for (CH₃)₃PO] to −12 kcal mol⁻¹ (for N₂). Moreover, for the monoanionic guests, the MEP values vary from −216 kcal mol⁻¹ (F⁻) to −125 kcal mol⁻¹ (PF₆⁻), in line with the interaction energies observed for their corresponding complexes. The SO₂⁻ dianionic guest exhibits the most negative MEP value (−247 kcal mol⁻¹) and the largest interaction energy (see Table 2).

As it appears from the data collected in Table 3, small isolated π-systems like ethene (50) and ethyne (51) bind to TCCP with about −5 kcal mol⁻¹. Small conjugated systems such as benzene (53) bind even stronger (about −7 kcal mol⁻¹), while larger condensed hydrocarbons (55–60) such as pyrene (58) bind stronger still (about −10 kcal mol⁻¹). As is apparent from the AIM analyses shown in Fig. 3, all these complexes are held together mainly by tetrel bonding interactions (in some cases perhaps stabilized by weak CN···HC polar contacts).

It is interesting to note that the binding energy peaks at coronene (60; −12.6 kcal mol⁻¹), which can be seen as a model for graphene. Likewise, the binding energies calculated with several fullerenes (61–64) are substantial and strongest for a model of carbon nanotube (12,0) at −12.6 kcal mol⁻¹ (64).

Also noteworthy is the positioning of TCCP over pyrene in 58 and triphenylene in 59; apparently TCCP prefers the periphery over the center. It is known what Li⁺ also preferentially binds to a peripheral ring in large condensed hydrocarbons.65 However, in 60 the TCCP sits perfectly above the center of the coronene.

Encouraged by the energies computed with small molecules and aromatic systems, we expected that Nature’s aromatic building blocks could bind to TCCP as well. The computational verifications of this expectation are listed in Table 3 as complexes 65–73 and Fig. 4 shows the molecular structure and AIM analysis of several representative examples. Models of tyrosine 65 (−8.1 kcal mol⁻¹) and tryptophan 66 (−11.7 kcal mol⁻¹) interact much like condensed hydrocarbons, binding to TCCP with their π-electrons. Histidine 67 (−11.6 kcal mol⁻¹) seems to prefer binding to TCCP with its N-atom. When protonated, histidine moves away from TCCP's electron poor binding pocket and instead establishes a strong hydrogen bond with one of the N-atoms in TCCP. The binding energies computed with the nucleobases (69–73) are very similar at

* Another geometry where pyridine interacts with its N-atom is more stable at −9.5 kcal mol⁻¹ (see also complex 22 Table 1). * No interaction with the π-system.

Next, we wondered how a host molecule with several appropriately-spaced TCCP units would interact with some size-complementary electron rich guests. To this end we conjured one bipodal and two tripodal claw-like hosts (Fig. S2, ESI†) in which the linking unit assures an appropriate space in between TCCP-moieties and also allows for the correct angles so that the C2(CN)₄ ‘binding pockets’ can face each other. We computed interacting energies with a selection of guests (see Table 4). The molecular geometries of selected complexes are shown in Fig. 5 (the whole series is shown in Fig. S3, ESI†). AIM analyses were also performed and revealed tetral bonding in all cases (not shown due to congested graphics).

The bipodal host interacts with some neutral and ‘flat’ molecules with about −5 to −10 kcal mol⁻¹ (74–77); while the interaction of the spherical halide anions is much larger about −11 kcal mol⁻¹. Adenine (69) and guanine (70) bind with their π-surfaces, while the thymine (71), cytosine (72) and uracil (73) interact with their lone-pair electrons on O and/or N and additional hydrogen bonding.

Table 4 Interaction energies (ΔE) and minimum contact distances (D) estimated at the DFT BP86-D3/def2-TZVP level of theory of complexes involving host molecules with multiple TCCP-units.

† Energies relative to unbound hosts in its energy minimal conformer (as estimated by a Monte Carlo MMFF simulation prior to the DFT minimum energy calculation). For geometries see Fig. S2 [compounds 88–90].
varying between −30 and −70 kcal mol⁻¹ (78–81). The two tri- podal hosts seem to complement the tetrahedral anions BF₄⁻ (82, 85), ClO₄⁻ (83, 86) as well as the trigonal planar NO₃⁻ (84, 87) with interacting energies of about −20 to −40 kcal mol⁻¹.

These energies are generally larger compared to the analogous interaction with a single TCCP unit (Tables 2 and 3). For example, 78 (−67.1 kcal mol⁻¹) is about 30% more stable than 44 (−52.08 kcal mol⁻¹) and 82 (−27.5 kcal mol⁻¹) is about 60% more stable than 48 (−17.17 kcal mol⁻¹). That the stabilization is not strictly additive is likely a result of some repulsive interactions in the complex (e.g. CN···NC), some strain on the conformation of the host (e.g. the Ar–C≡C–CH₂ units in 82 and 84 are not perfectly linear), and/or the decreased electronegativity of the guest upon binding to one TCCP moiety.

**Discussion and conclusions**

From the above results it is clear that TCCP derivatives can accommodate a plethora of guest molecules that bear lone-pair electrons, π-electrons and/or a negative charge. The main mode of interaction with these electron rich entities is tetrel bonding with TCCP's electron deficient C₂(CN)₄ bowl. Hydrogen bonding with the cyano N-atoms may further stabilize the complex (e.g. complex 6 with THF).

The binding energies of about −10 kcal mol⁻¹ observed with various neutral guest molecules are comparable in strength to strong hydrogen bonding involving charge-neutral H-bonding pairs.⁶⁶ The values of about −15 to −30 kcal mol⁻¹ – typically observed with various anions – is truly remarkable because they are comparable in strength to very strong (ionic) hydrogen bonding.⁶⁶ The exceptionally large enthalpies computed for H⁻ (−43.4 kcal mol⁻¹) HO⁻ (−57.7 kcal mol⁻¹) and F⁻ (−52.1 kcal mol⁻¹) even far exceed the common benchmark for strong hydrogen bonding (about −35 kcal mol⁻¹).⁶⁶

The large energies of formation computed between TCCP and (models of) fullerenes (about −10 kcal mol⁻¹) was somewhat expected, as TCCP's bowl-like shape and electron positive core are complementary to the concave shape and electron rich surface of fullerenes. This complementarity hints towards the potential of TCCP derivatives to act as facial amphiphiles to help mobilize these carbon isomers in solution.⁵⁷–⁷⁰ Other charge-neutral supramolecular approaches for binding fullerenes indeed seem far less apt. For example, typical binding energies of hydrogen-π and halogen-π interactions are estimated at about 1–5 kcal mol⁻¹,⁷¹,⁷² while not being shape-complementary to fullerenes at all.

Perhaps the most important result is the difference in geometric preferences of TCCP binding to (models of) amino acids and nucleobases. This implies that TCCP derivatives might selectively nest themselves in proteins and DNA/RNA-type molecules. In this context it is worth mentioning that TCCP derivatives are expected to be poorly hydrated in aqueous solution (no strong H-bond donors) and thus also interact with biomolecules by virtue of the hydrophobic effect. The potential of TCCP derivatives to bind strongly and selectively to biomolecules implies that TCCP might be engineered to influence the functioning of biomachineries, which in turn might have pharmacological implications. Additionally, the bipodal and tri-podal TCCP hosts illustrate that strategically placed TCCP-units may greatly enhance the affinity for a guest molecule, just like multiple H-bond donors within a protein can result in high affinity binding to a ligand.

In summary we highlighted that TCCP is an accessible supramolecular synthon that acts as an 'electron sponge', mainly by virtue of tetrel bonding interactions. Its unique bowl-like shape, electron deficient core, and (presumed) hydrophobic character make TCCP-derivatives a promising new addition to the (bio)chemists toolbox (e.g. the PDB is void of TCCP-like ligands). As a result, following this theoretical exploration we anticipate that experimental exploitation of this unit will soon unveil its functional potential.
