Hass avocado modulates postprandial vascular reactivity and postprandial inflammatory responses to a hamburger meal in healthy volunteers

Zhaoping Li,* Angela Wong, Susanne M. Henning, Yanjun Zhang, Alexis Jones, Alona Zerlin, Gail Thames, Susan Bowerman, Chi-Hong Tseng and David Heber

Hass avocados are rich in monounsaturated fatty acids (oleic acid) and antioxidants (carotenoids, tocopherols, polyphenols) and are often eaten as a slice in a sandwich containing hamburger or other meats. Hamburger meat forms lipid peroxides during cooking. After ingestion, the stomach functions as a bioreactor generating additional lipid peroxides and this process can be inhibited when antioxidants are ingested together with the meat. The present pilot study was conducted to investigate the postprandial effect of the addition of 68 g of avocado to a hamburger on vasodilation and inflammation. Eleven healthy subjects on two separate occasions consumed either a 250 g hamburger patty alone (ca. 436 cal and 25 g fat) or together with 68 grams of avocado flesh (an additional 114 cal and 11 g of fat for a total of 550 cal and 36 g fat), a common culinary combination, to assess effects on vascular health. Using the standard peripheral arterial tonometry (PAT) method to calculate the PAT index, we observed significant vasoconstriction 2 hours following hamburger ingestion (2.19 ± 0.36 vs. 1.56 ± 0.21, p = 0.0007), which did not occur when the avocado flesh was ingested together with the burger (2.17 ± 0.57 vs. 2.08 ± 0.51, NS p = 0.68), Peripheral blood mononuclear cells were isolated from postprandial blood samples and the Ikappa-B alpha (IkBalpha) protein concentration was determined to assess effects on inflammation. At 3 hours, there was a significant preservation of IkBalpha (131% vs. 58%, p = 0.03) when avocado was consumed with the meat compared to meat alone, consistent with reduced activation of the NF-kappa B (NFkB) inflammatory pathway. IL-6 increased significantly at 4 hours in postprandial serum after consumption of the hamburger, but no change was observed when avocado was added. Postprandial serum triglyceride concentration increased, but did not further increase when avocado was ingested with the burger compared to burger alone despite the added fat and calories from the avocado. These observations are suggestive of beneficial anti-inflammatory and vascular health effects of ingesting added Hass avocado with a hamburger patty.

Introduction

Atherosclerosis is one of the main causes of morbidity and mortality in the Western world. Several hypotheses have been articulated to explain the initiating events in atherosclerosis, but its pathogenesis seems to be multifactorial.1 Over the past twenty years, the contribution of oxidation of lipoproteins including cholesterol and LDL cholesterol to the development of atherosclerosis has been demonstrated in both basic and clinical studies.2 Endothelial dysfunction contributes to atherosclerosis3 and is characterized by a decreased bioavailability of nitric oxide and increased expression of proinflammatory cytokines.4 The use of antioxidants and anti-inflammatory natural products from dietary sources, such as fruits and vegetables including avocados, has been proposed as an adjunct to other preventive measures such as achieving and maintaining a healthy body weight, and controlling blood cholesterol levels with drugs.

High-calorie meals rich in saturated fat and carbohydrate can lead to transient exaggerated elevations in blood glucose, free fatty acids, and triglycerides. This condition, termed postprandial dysmetabolism, generates excess free radicals (or reactive oxygen species). The ensuing oxidative stress triggers a biochemical cascade throughout the circulation, inducing inflammation, and endothelial dysfunction. These postprandial changes, when repeated multiple times each day, can create a milieu conducive to the development of atherosclerotic risk factors and coronary heart disease (CHD), the main cause of morbidity and mortality in the Western world.5–8

The stomach is a prime location for interactions of these antioxidant compounds with lipids and other food constituents...
prone to oxidation. The stomach acts as a bioreactor and gastric fluid as a medium for further dietary lipid peroxidation and/or antioxidation. The gastrointestinal tract is constantly exposed to dietary oxidized food compounds produced during the processing and storage of foods or during their digestion in the stomach. The idea that the gastrointestinal tract is the location for the protective activity of antioxidants was presented by Halliwell et al.11

The avocado contains monounsaturated fats, lutein, glutathione, vitamin E, and phenolic antioxidants.12,13 It has a similar calorie density to other fruits and vegetables due to its high water content. Avocados are rich in oleic acid, similar to what is found in olives and olive oil. However, there is limited information on the anti-oxidant/anti-inflammatory properties of avocados in humans. It has been reported that avocado-enriched diets resulted in improvements in lipid profiles when compared to a high-carbohydrate diet in healthy subjects14 and those with Type 2 DM.15 In addition it was demonstrated that total cholesterol and LDL cholesterol concentrations were significantly decreased in mildly hypercholesterolemic patients consuming an avocado-rich diet.16

In the present pilot study we examined the effect of avocado added to hamburger meat, a common culinary combination, on postprandial vascular health and anti-inflammatory activity in healthy subjects.

Materials and methods

Study subjects

The study utilized a randomized crossover design and included 11 healthy male volunteers. The study protocol was approved by the University of California Los Angeles (UCLA) Institutional Review Board. All subjects gave written informed consent prior to any study procedures being conducted. Subjects were excluded if they had metabolic disorders, were taking dietary supplements, smoked >1 cigarette per day, exercised heavily (aerobic exercise more than four times for 30 min per week), or drank more than 2 glasses of wine, 2 cocktails or two beers per day. Each subject was seen at the research clinic on two separate occasions separated by at least one week. Subjects consumed, in a random order, two different test meals consisting of either: (a) a ground beef patty seasoned with salt, or (b) a ground beef patty seasoned with salt and 68 grams of avocado. The subjects were asked to avoid eating meat, poultry, fish or avocado products for 3 days before the day of each of the two experimental visits.

Test meals

Hamburger patties were prepared in the UCLA General Clinical Research Center kitchen. The beef with 10% of fat was weighed, minced in a large Kitchen Aid mixer bowl for 2 minutes at the lowest setting mixed with 1 g of salt. Using a 5 3/4 inch ring mold the meat was divided into 250 g patties and flattened. They were cooked to an internal temperature of 77 degrees centigrade, frozen and packaged in the UCLA General Clinical Research Center kitchen. They were delivered frozen to the UCLA Center for Human Nutrition. The patties were then reheated in their packaging using a boiler at the UCLA Center for Human Nutrition to approximately 60°C. The two test meals consisted of either a burger alone or same burger with avocado with a glass of water (200 ml). Fresh, ripe Hass avocados (provided by the Hass Avocado Board) were sliced into halves; 68 grams were scooped from one half and weighed. The avocado portion was prepared into a mash and added to the hamburger.

Study protocol

Participants arrived at the UCLA Center for Human Nutrition after fasting for 10 hours. After an indwelling catheter was inserted into the vein of the forearm and a blood sample was taken, the first measurement of peripheral arterial tonometry (PAT) was performed. The subjects were then provided either the burger or burger and avocado to be eaten within 30 min. Blood samples were drawn again at 1, 2, 3, 4, 5, 6 h after the meal for triglyceride and nitric oxide analyses. PAT was repeated after 2 hours. Urine was collected in a 2 L container for 6 h after the meal. Urine volume was recorded and aliquots were taken for analysis of nitric oxide and creatinine.

Peripheral arterial tonometry

Using established methods,17 a blood pressure cuff was placed on one upper arm (study arm), while the other arm served as a control (control arm). Peripheral arterial tonometry probes were placed on one finger of each hand for continuous recording of the PAT signal. After a 10 min equilibration period, the blood pressure cuff will be inflated to suprasystolic pressures for 5 min. Then the cuff was deflated, while PAT recording was continued for 10 min. Reactive hyperemia-peripheral arterial tonometry (RH-PAT) data were analyzed by a computer in an operator-independent manner as previously described.18

Biochemical analysis

EDTA plasma and serum were separated from whole blood by centrifugation (910 g, 15 min), frozen, and kept at −80°C. Serum triglyceride concentration was determined using standard enzymatic methods. Reagents, standards and calibrators were purchased from Pointe Scientific (Lincoln Park, MI). The interassay coefficients of variation are less than 4% and intra-assay coefficients of variation are less than 2%. Concentrations of total nitrate and nitrite (NOx) were measured in serum samples by a chemiluminescence method. Serum samples (1:10 dilution) were filtered through ultrafilter (PL-10 Ultrafree MC centrifugal filter units; Millipore Corp., Bedford, MA) and centrifuged for 1 h at 2500 × g. After removing high-molecular proteins, the filtered serum sample was injected into the reaction chamber of the NO analyzer, and refluxed in glacial acetic acid containing sodium iodide. Nitrate and nitrite in the serum were reduced to NO, which, after reacting with ozone were quantified by a chemiluminescence detector (NOA 280i, Sievers Instruments, Boulder, CO). The concentration was determined in comparison to a sodium nitrate standard calibration curve.
Cytokine enzyme-linked immunosorbent assays (ELISAs)

IL-6, IL-8, and TNF-alpha (TNF-α) protein levels were measured in plasma of 9 participants using eBioscience Platinum ELISA kits according to manufacturer’s instructions. Plasma of two participants was omitted due to hemolysis. Briefly, after a prewash of the wells with PBS + 1% Tween-20 (wash buffer), cytokine standards or plasma diluted with an equal volume of a sample diluent for IL-8 and TNF-α or assay buffer (PBS + 1% Tween-20 + 10% bovine serum albumin) for IL-6. The appropriate biotin-conjugated antibody was diluted in the assay buffer and incubated with the standard or samples for 2 hours on a microplate shaker at 100 rpm at RT. Following 4 washes with the wash buffer, diluted streptavidin–HRP in the assay buffer was incubated in standard and sample wells for 1 hour on a microplate shaker. After washing unbound streptavidin–HRP 4 times with the wash buffer, a tetramethyl–benzidine substrate solution is added to wells. After 10 min, a 1 M phosphoric acid stop solution is added to stop the enzymatic color development in all samples. Absorbance was read at 450 nm for the primary wavelength with a 620 nm reference wavelength on a microplate reader (Molecular Devices; Sunnyvale, CA). Interassay coefficients of variation were between 5 and 8% and intraassay coefficients of variation were between 3 and 6%. Grossly hemolyzed samples were excluded from analysis.

IkB-α protein expression in peripheral blood mononuclear cells (PBMCs)

PBMCs were isolated from Na-EDTA tubes according to methods described by Aljada et al., 2004. After cells were washed with Hank’s buffered saline solution, they were lysed with a whole cell lysis buffer (Millipore; Temecula, CA). Total protein concentrations in PBMC lysates were measured by the bicinchoninic acid protein assay (Pierce; Rockland, IL). Equal amounts of protein (40 μg) were then loaded onto 10% gradient gels (Amersham Biosciences, Uppsala, Sweden) and electrophoresed at 100 V. Gels were transferred to a nitrocellulose membrane using the manufacturer’s suggested protocol. Membranes were blocked using 5% (w/v) bovine serum albumin (BSA) in Tris-buffered saline containing 0.001% (v/v) Tween-20 before probing with rabbit polyclonal IkB-α (C-15) antibody (Santa Cruz Biotechnology; Santa Cruz, CA) overnight at 4 °C. After washing the unbound primary antibody, the HRP-conjugated goat anti-rabbit secondary antibody was incubated with the membrane for 2 h at RT. Final chemiluminescence detection was based on an ECL+ kit (Amersham Biosciences, Uppsala, Sweden) as per the manufacturer protocol on a BioRad ChemiDoc XRS (BioRad; Hercules, CA). Membranes were then stripped and reprobed with a mouse monoclonal antibody for beta-actin (Abcam; Cambridge, MA) to ensure equal protein loading. Protein expression was quantified using densitometry on digitized images with the QuantityOne software (BioRad).

Statistics

Data were expressed as mean ± standard deviation. Because this is a cross-over design, we used the paired t-test to compare postprandial biomarkers for each time point. To assess the overall difference, we also use the linear mixed effects model to compare postprandial biomarkers over time. An auto-regressive correlation matrix was used to accommodate the correlation from the same subject. All tests were two sided, and differences were considered significant at P < 0.05. SAS 9.1.3 software package was used.

Results

Eleven male subjects met both the inclusion and exclusion criteria and were enrolled and completed the study. The characteristics of the subjects are shown in Table 1. The burgers and study protocol were well tolerated and none of the subjects had any adverse event. The baseline PAT score was 2.20 ± 0.36 for participants consuming hamburger only and 2.17 ± 0.57 for those consuming hamburger and avocado. Two hours after the consumption of the test burger, the PAT score was decreased by 27.4 ± 16.6% (2.20 ± 0.36 vs. 1.56 ± 0.21, p = 0.0007) which was prevented when avocado was ingested with the burger (2.17 ± 0.57 vs. 2.08 ± 0.51, NS p = 0.68). The change of PAT score after hamburger versus hamburger + avocado consumption was approaching significant difference (p = 0.052) (Fig. 1B).

The serum nitrate and nitrite concentrations showed a trend to decrease starting at 1 hour post-consumption of hamburger and continued a nonsignificant decrease throughout the following 5 hours. The addition of avocado to hamburger did not change the decrease of postprandial serum nitrite and nitrate levels at any time point (Fig. 2).

Postprandial plasma IL-6 levels increased by ~70% at 4 hours with burger only but this increase was attenuated when avocado was ingested with the burger despite the added fat and calories from the avocado (Fig. 3A). Neither burger nor burger + avocado affected the postprandial plasma TNF-alpha levels (Fig. 3B). Plasma IL-8 protein was also measured, but levels were below ELISA detection limits in plasma (data not shown).

To further investigate the postprandial effect of avocado on inflammation, PBMCs were isolated from postprandial blood samples and IkB-α protein concentration was analyzed as an inverse marker of stimulation of NFkB. NFkB is one of the most important transcription factors in the induction of inflammatory processes.29 NFkB is located in the cytoplasm in an inactive form bound to IkB-α. Upon stimulation IkB-α is phosphorylated and degraded and NFkB is translocated to the nucleus to induce the transcription of pro-inflammatory genes.

and NFκB is released and translocated to the nucleus. IkB-α undergoes ubiquination and degradation via proteasome activity. Therefore stimulation of NFκB is associated with a decrease in IkB-α concentration. Following the burger consumption, IkB-α protein levels decreased in PBMC lysates, suggesting a NFκB pathway activation. However, when avocado was added to the burger, IkB-α protein levels were only slightly elevated. By 3 hours, IkB-α protein was significantly preserved after the consumption of the burger + avocado compared to the burger alone (131% vs. 58%, p = 0.03), suggesting that avocado inhibited peripheral inflammation via the NFκB pathway (Fig. 4).

There was a significant increase in the postprandial concentration of triglycerides in blood from participants consuming the burger at hours 2, 3 and 4. The level peaked at hour 3, remained high at the end of hour 4 and trended down at hour 5. Addition of avocado did not increase the triglyceride level any further (Fig. 5).

**Discussion**

The presented results from this small pilot study demonstrated for the first time that the addition of avocado to a high fat meal was able to attenuate the postprandial vasoconstrictive effect of a high fat diet. Potential mechanisms for the health beneficial effects may be related to an increase in plasma concentration of the monounsaturated fatty acid oleic acid as shown by Pieterse et al. They recently examined the effects of avocados as part of an energy-restricted diet on weight loss, serum lipids and vascular function in overweight and obese subjects randomly assigned to consume energy-restricted diets with total energy intakes of 30% fat, 55% carbohydrates and 15% protein. The experimental group consumed 200 g per day of avocado (30.6 g fat), which was substituted with 30 g dietary fat in the control group. While the avocado-enriched diet had no effect on serum lipids, a significant increase in plasma oleic acid was observed. Partial replacement of complex digestible carbohydrates with monounsaturated fatty acids (avocado as one of its main sources) in the diet of patients with NIDDM also favorably improved both lipid profiles and glycemic control.

While the avocado is an increasingly popular fruit rich in monounsaturated fats, most studies on the benefits of monounsaturated fats have focused on nuts and olive oil with inconsistent outcomes. A study by Cortes et al. demonstrated that the addition of walnut was associated with postprandial vasodilation in patients with hypercholesterolemia, whereas olive oil was associated with vasoconstriction. Both did not show an effect in healthy participants. However, the combination of red wine and green olive oil led to vasodilation, while there was no benefit from the addition of white wine and olive oil.
Chronic inflammation may play a role in the development of atherosclerosis and cardiovascular diseases. Previous epidemiological studies have associated IL-6 with atherosclerosis and increased risk for cardiovascular diseases. High-fat meals have been shown to influence plasma inflammatory biomarkers such as IL-6, TNF-α, and CRP. Cytokines, through inhibition of eNOS and the reduction of nitric oxide formation, effect blood vessel constriction. Foods high in antioxidant and anti-inflammatory phytochemicals, such as tomatoes and strawberries, were shown to inhibit these biomarkers. Results presented here demonstrated that the addition of avocado, rich in monounsaturated fatty acids and antioxidants, attenuated the postprandial increases in plasma IL-6 induced by a high-fat meal in healthy individuals. This supports the hypothesis that avocado, although energy rich, may provide cardioprotection.

The NFκB signaling pathway is a key immune and inflammatory response pathway underlying atherosclerosis and
High-fat meals were shown to induce postprandial NFκB in PBMCs which could be inhibited by the consumption of red wine. Meals enriched with butter, but not olive oil or walnut, induced NFκB in PBMCs, suggesting that the monounsaturated fatty acids in walnut and olive oil may be beneficial in preventing postprandial inflammation. Another study by Perez-Martinez, 2007, demonstrated that consumption of a Mediterranean diet rich in olive oil did not increase NFκB stimulation compared to the consumption of a Western diet.

Polyphenols from fruits, vegetables, tea and cocoa have been proposed to improve the endothelial function through nitric oxide (NO) mediated relaxation. However, we did not find any change in NO concentration in the serum collected following the burger + avocado intervention compared to that following the burger intervention. Other potential mechanisms regulating the endothelial function may have been involved. For example the polyphenol-induced endothelium-dependent relaxation also involves the endothelium-derived hyperpolarizing factor,
Besides NO, in several types of arteries. Red wine polyphenols have been shown to prevent endothelin 1 induced vascular O$_2^-$ production by reducing overexpression of p47phox and the subsequent increased NADPH oxidase activity, leading to improvement in endothelial function. Resveratrol, a polyphenol from grape, was shown to inhibit uterine contraction by blocking external Ca$^{2+}$ influx induced by PGE$_2$ and high K$^+$ concentrations. Avocado may also change the fatty acid profile leading to the alteration of, for example, the fatty acid metabolite prostacyclin (PGI2). In summary it appears more likely that avocado may act through other factors influencing the endothelial function other than NO mediated relaxation.

Results from the present pilot study demonstrated that the common culinary practice of adding 1/2 of an avocado (68 g) to a hamburger patty may reduce pro-inflammatory and vasoconstrictory effects of a postprandial challenge with meat patty. In summary we demonstrated that in healthy participants the consumption of 250 g of beef led to a significant decrease in vascular reactivity, increase of serum IL-6 and NFkB activation in PBMCs. The popular practice of adding a slice of avocado to various meat sandwiches was able to reduce these symptoms and may have cardiovascular health benefits. Larger intervention studies are needed to confirm these results.

Acknowledgements

None of the authors had any conflict of interest at the time the research was done. Z. Li, S.M. Henning and D. Heber designed the research and wrote the paper; Y. Zhang, A. Wong, A. Jones, A. Zerlin, G. Thames, and S. Bowerman conducted the research and C.H. Tseng performed statistical analysis. All authors read and approved the final manuscript. This study was supported by the Hass Avocado Board.
