A multinuclear $^1$H, $^{13}$C and $^{11}$B solid-state MAS NMR study of 16- and 18-electron organometallic ruthenium and osmium carborane complexes

Nicolas P. E. Barry,* Thomas F. Kemp,b Peter J. Sadler*ab and John V. Hanna*b

Introduction

The icosahedral structure of dicarba-closo-dodecaborane (boron- and carbon-cluster; C$_6$B$_{10}$H$_{12}$) results in a slight negative polarization of the 10 hydrogen atoms. These clusters contain characteristic non-classical bonding interactions: the hexacoordination of the carbon and boron atoms results in electron-deficient bonding and spreading of the bonding power of a pair of electrons over more than two atoms. The aggregation of atoms in 3-centre-2-electron bonding compensates for this low electron density. The electron-deficient complexes [Ru/Os(p-cym)(1,2-dicarba-closo-dodecaborane-1,2-dithiolate)] are reported. The MAS NMR data from these 16-electron complexes are compared to those of free carborane-ligand and an 18-electron triphenylphosphine ruthenium adduct, and reveal clear spectral differences between 16- and 18-electron organometallic carborane systems in the solid state.

Results and discussion

Free ligand 1 was synthesised by reaction of dicarba-closo-dodecaborane with two mol equiv of n-butyl lithium (nBuLi) in dry THF under nitrogen and by addition of sulfur powder. After removal of the solvent, the compound was used without further purification. The $^1$H MAS NMR spectrum of 1 shows the proton resonance of the BH vertices at 5.0 ± 0.1 ppm, along with a broad signal at 2.3 ± 0.2 ppm (Table 1). Similarly, a $^{13}$C MAS NMR resonance assignable to the carborane carbon atoms was found at 94.7 ± 0.1 ppm in the spectrum of 1, similar to the shift in solution (Table 2), while three other signals were observed at 69.4 ± 0.1, 26.0 ± 0.1 and 15.1 ± 0.1 ppm. No attempt was made to assign the latter peaks, but they may belong to other sulphide species in the reaction mixture.

The 16-electron complexes 2 and 3 were synthesised following a published procedure, involving the reaction of ligand 1...
with the corresponding ruthenium or osmium dimer [Ru/Os-(p-cym)Cl₂]₂ under a nitrogen atmosphere. After purification by column chromatography on silica gel, the two compounds were isolated as powders. Both ¹H and ¹³C MAS NMR spectra of 2 and 3 are characterised by similar resonances. The ¹H MAS NMR resonances of the two complexes are broad and unresolved, but display the same overall characteristics of a strongly dipolar-coupled system, while the corresponding ¹³C MAS NMR spectra are remarkably well resolved. The carbon signals of the carborane ligand are found at 101.8 ± 0.1 and 98.7 ± 0.1 ppm, for 2 and 3 respectively. The CH carbon signal of the para-cymene ligand is observed at 34.7 ± 0.1 ppm for 2 and 3, respectively, while the methyl carbons of the methyl and isopropyl groups are found at 27.0 ± 0.1, 22.4 ± 0.1, 21.7 ± 0.1 ppm, respectively. As expected, six signals are observed for the aromatic carbons of the arene ligand. These data are summarised in Table 1 and shown in Fig. 2.

The 18-electron complex 4, synthesised by addition of triphenylphosphine to 2, according to literature, also exhibits a well-resolved ¹³C MAS NMR spectrum showing similar signals as 2 and 3, plus the 6 resonances associated with the triphenylphosphine ligand at 140.8 ± 0.1, 138.6 ± 0.1, 135.2 ± 0.1, 133.0 ± 0.1, 130.4 ± 0.1, 129.3 ± 0.1 ppm. Interestingly, the carborane ¹³C signal in 4 is shifted upfield to 126.5 ± 0.1 ppm.

![Fig. 2](image-url) ¹H MAS and ¹³C CPMAS NMR spectra of free ligand 1, 18-electron complex 4 and 16-electron complexes 2 and 3. The ¹³C resonances between 150 and 200 ppm for 1–4 are assignable to spinning sidebands, as are bands between 50 and 60 ppm in the spectrum of complex 4.
comparison to the corresponding resonances for 2 and 3 which are observed at ~100 ppm. This shift may arise from the loss of pseudo-aromaticity between 16- and 18-electron species and elongation of the C−S bonds. X-ray crystal structures of the electron-deficient osmium-carborane complex 3 (CCDC 166814)\textsuperscript{14} and 18-electron ruthenium complex 4 (CCDC 136420)\textsuperscript{5} have been previously reported. This carborane $^{13}$C MAS NMR resonance might therefore be a useful probe for the 16- or 18-electron configurations of an arene metal carborane complex, and suggests that the complex 2, for which no X-ray crystal structure is available, is indeed an electron-deficient complex in the solid state. The chemical shifts of most of the $^{13}$C signals observed in CDCl\textsubscript{3} solution (Table 2) are very similar to those observed in the solid state and also are in accord with previous SSNMR studies on arene ruthenium complexes (Table 3).\textsuperscript{15}

Clear NMR spectroscopic differences between 16- and 18-electron complexes are also observed from the 1D $^{11}$B MAS and 2D $^{11}$B multiple quantum magic angle spinning (MQMAS) NMR data of complexes 2−4 (see Fig. 3). 2D MQMAS NMR experiments on half-integer quadrupolar nuclei often provide increased resolution as the narrower central transition resonances are distributed along a second dimension.\textsuperscript{16−18} The 2D $^{11}$B MQMAS spectrum of the free ligand 1 exhibits three well resolved resonances with apparent shifts in the 2−13 ppm range. Although four inequivalent B positions are expected from the schematic representation of 1 in Fig. 1, positions B\textsubscript{6,10}H and B\textsubscript{9,12}H are not resolved and the intensity ratio of the manifold of resonances is 4:4:2 instead of 2:2:4:2. Similarly, the 2D $^{11}$B MQMAS data from the 18-electron complex 4 also exhibit three resonances with positions B\textsubscript{6,10}H and B\textsubscript{9,12}H again not being resolved. These observations contrast markedly with the 1D $^{11}$B MAS and 2D $^{11}$B MQMAS NMR data from the 16-electron complexes 2 and 3 which show single broadened resonances at −9.3 ± 0.5 and −10.3 ± 1, respectively. The results for 2 and 3 suggest that significant motional averaging is occurring on the timescale of the NMR experiment, due to either full or restricted rotation of the carborane cage and its pendant metallocene linker, yielding an averaged spectrum represented by a single broadened resonance. This contrasts with the unaveraged/resolved 2D $^{11}$B MQMAS result from the 18-electron complex 4 which is unlikely to possess the same rotational freedom due to the bulky additional PPh\textsubscript{3} group stabilizing this structure. The additional PPh\textsubscript{3} ligand in complex 4 is evident from the $^{31}$P MAS NMR spectrum shown in Fig. 3 where one major resonance is observed at 32.5 ± 0.1 ppm; this $^{31}$P shift for PPh\textsubscript{3} is located further downfield and deshielded in comparison to other transition metal PPh\textsubscript{3} adducts involving Cu and Ag.\textsuperscript{19,20} This observation is also in agreement with corresponding $^{31}$P solution NMR measurements where a similar shift at 31.19 ppm is observed for complex 4 in CDCl\textsubscript{3} solution.

Solid state MAS NMR spectroscopy has been only rarely employed for the study of the molecular structures of ruthenium and osmium complexes and carborane-containing systems. Some reported examples of MAS and static NMR studies for such compounds are listed in Table 3. This study demonstrates that MAS NMR spectroscopy is a potentially powerful tool for probing the electronic structures of arene metal carborane complexes in the solid state, and highlights some particular spectral characteristics, which can aid differentiation between 16- and 18-electron systems. Further work is needed to elucidate the nature of the dynamic motion which appears to be associated with the carborane cage and its pendant metallocene linker for the 16-electron complexes 2 and 3 (in comparison to their 18-electron counterpart 4), as initially observed through the $^{11}$B MAS NMR studies. Further $^{11}$B, $^1$H and $^2$D solid state NMR studies should help to clarify this phenomenon.

### Conclusions

The interconversion of 16- and 18-electron organometallic arene complexes is of particular importance in the design of Ru catalysts, e.g. for azide−alkyne cycloaddition reactions,\textsuperscript{27} racemisation of aromatic and aliphatic secondary alcohols,\textsuperscript{28} and for transfer hydrogenation.\textsuperscript{29} The conversion from 16- to 18-electron carborane-containing organometallic complexes has also been shown to be a useful synthetic strategy for

multimetallic clusters containing direct metal–metal bonds.\textsuperscript{30,31} Sixteen-electron complexes are often thought to be reactive intermediates in catalytic cycles but can be difficult to isolate and characterise. In solution solvent molecules may bind weakly to the vacant 6th coordination site. Equilibria can exist in solution between 16- and 18-electron species, for example between electron-deficient complex \([\text{Ru}(\eta^6-\text{p-cym})(1,2\text{-dicarba-closo-dodecaborane-1,2-dithiolate})]\) (2) and corresponding 18-electron amine and phosphine adducts (e.g. 4).

Here we have used multinuclear solid state MAS NMR to characterise the stable 16-electron complex \([\text{Ru}(\eta^6-\text{p-cym})(1,2\text{-dicarba-closo-dodecaborane-1,2-dithiolate})]\) and its Os\textsuperscript{II} analogue (3). The comparison of \(^1H\), \(^{13}C\) and \(^{11}B\) solid-state NMR spectra of 16-electron ruthenium complex 2 with the 16-electron osmium complex 3 and 18-electron ruthenium complex 4, complexes which have been characterised by X-ray crystallography, provided a clear structural correlation between electron deficient complexes 2 and 3, and highlighted some differences between 16- and 18-electron complexes 2 and 4. The increased resolution afforded by the 2D \(^{11}B\) MQMAS NMR technique has highlighted possible dynamic processes affecting the carborane cage in the 16- and 18-electron structures. Further \(^{11}B\), \(^1H\) and \(^2\H\) solid state NMR studies may be fruitful for charactering such dynamics.

**Experimental section**

**Materials**

The syntheses of the ligand \([(1,2\text{-dicarba-closo-dodecaborane-1,2-dithiolate})\text{Li}_2]\), 16-electron precursors \([\text{Ru}(\eta^6-\text{p-cym})(1,2\text{-dicarba-closo-dodecaborane-1,2-dithiolate})]\) (2), \([\text{Os}(\eta^6-\text{p-cym})(1,2\text{-dicarba-closo-dodecaborane-1,2-dithiolate})]\) (3), and the 18-electron complex \([\text{Ru}(\eta^6-\text{p-cym})(1,2\text{-dicarba-closo-dodecaborane-1,2-dithiolate})(\text{triphenylphosphine})]\) (4) were based on a previous report.\textsuperscript{6} All the complexes were purified by column chromatography on silica gel, using a mixture 2/1 hexane–dichloromethane. The purity of the complexes was assessed by \(^1H\) NMR spectroscopy in CDCl\textsubscript{3} and was in accord with previous reports.

**Methods and instrumentation**

All \(^{13}C\) MAS NMR data were acquired at 11.7 T using a Bruker Avance III spectrometer (\(^{13}C\) Larmor frequency of 125.76 MHz). The \(^1H–^{13}C\) cross-polarisation experiment was used in each case, with these measurements being performed using a Bruker 4 mm triple-channel HXY probe operating at a MAS frequency of 10 kHz. An initial \(^1H\) \(\pi/2\) excitation pulse of 2.5 \(\mu\)s, a Hartmann–Hahn contact period of 1 ms and a recycle delay of 3 s were used throughout. All \(^{13}C\) isotropic chemical shifts were referenced to the primary reference of TMS via the secondary reference of solid alanine. The \(^{31}P\) MAS NMR data for complex 4 was acquired at 14.1 T using a Bruker Avance II+ spectrometer (\(^{31}P\) Larmor frequency of 243.81 MHz) and a Bruker 4 mm triple channel HXY probe operating at a MAS frequency of 12 kHz. A single pulse experiment was used employing a \(^{31}P\) \(\pi/4\) excitation pulse of 2.5 \(\mu\)s and a recycle delay of 30 s. \(^{31}P\) chemical shifts were referenced to the primary reference of 85\% H\textsubscript{3}PO\textsubscript{4} via a secondary solid reference of \((\text{NH}_4)\text{H}_2(\text{PO}_4)\). The 1D \(^{11}B\) MAS NMR data were acquired at 14.1 T using Varian 600 spectrometer (\(^{11}B\) Larmor frequency of 193.23 MHz) and a Bruker 4 mm T3 probe operating at a MAS frequency of 12 kHz. A single pulse experiment was used employing a \(^{11}B\) \(\pi/2\) ‘selective’ (solids) pulse of 3 \(\mu\)s and a recycle delay of 5 s. All apparent \(^{11}B\) chemical shifts are...
referred to NaBH₄ and do not represent isotropic values as they remain uncorrected for second order quadrupole effects. The corresponding 2D ^1H MQMAS NMR data were acquired at 14.1 T using a Bruker Avance II+ spectrometer and a Bruker 3.2 mm triple-channel HXY probe operating at a MAS frequency of 20 kHz. A 3Q Z-filtered experiment was used with a recycle delay of 4 s. Finally, all ^1H MAS NMR measurements were undertaken using a Bruker Avance II+ spectrometer (^1H Larmor frequency of 600.1 MHz) and a Bruker 2.5 mm triple channel HXY probe operating at a MAS frequency of 30 kHz. A single pulse experiment was used employing a ^1H π/4 excitation pulse of 2 μs and a recycle delay of 30 s. All ^1H chemical shifts were referenced to the primary reference of TMS.
