The combination of acidic zeolites and Fischer–Tropsch synthesis (FTS) catalysts for one-step production of liquid fuels from syngas is critically reviewed. Bifunctional systems are classified by the proximity between FTS and acid functionalities on three levels: reactor, catalyst particle, and active phase. A thorough analysis of the published literature on this topic reveals that efficiency in the production of liquid fuels correlates well with the proximity of FTS and acid sites. Moreover, possible side reactions over the FTS metal, including direct CO hydrogenation and hydrocarbon hydrogenolysis, are addressed. The contribution of these side reactions should carefully be considered and separated from that of the zeolite function when evaluating the performance and product spectrum of zeolite-containing catalysts.

1. Introduction

Due to their high volumetric and reasonable mass energy densities and low cost/price, gasoline and diesel are the preferred transportation fuels. To date, these liquid fuels are being mainly produced in conventional refineries from crude oil. Depletion of petroleum and environmental concerns have

driven a worldwide research on alternative processes for the production of energy carriers. Among the various possibilities and chemical conversion routes, syngas (a mixture of CO and H₂) production followed by Fischer–Tropsch synthesis (FTS) holds promises for extensive implementation in the near future. This is due to the maturity of both technologies in addition to abundance of alternative resources such as natural gas, coal, and biomass. Furthermore, the dependency on centralized fossil-based reservoirs may be relaxed if globally dispersed raw materials can be utilized as feedstock.

When producing liquid fuels by the state of the art gas-to-liquid (GTL) processes, low-temperature Fischer–Tropsch (LTFT)

Sina Sartipi

Sina Sartipi (1981) is a chemical engineer, specialized in the field of heterogeneous catalysis. After obtaining his MSc from the University of Tehran (Iran), he did his PhD at Delft University of Technology (Netherlands, 2014). Currently, he is a postdoctoral researcher at Delft University of Technology and the highlighted research topics that he is involved in include heterogenization of hydroformylation catalysts, utilization of metal organic frame-

works (MOFs) for heterogeneous catalysis and development of Fischer–Tropsch synthesis catalysts. The latter was the main area of his PhD research as well. He has co-authored nine peer reviewed articles.

Michiel Makkee

Michiel Makkee (1954) did his master and PhD studies on catalysis and organic chemistry at the Delft University of Technology. After more than 6 years at Exxon Chemicals he was nominated as associate professor in the field of Catalysis Engineering and Process Development at the Delft University of Technology (1990). He was nominated as special part time professor at the Politecnico di Torino (2011). He is (co-)inven-

tor of 25 patents and (co-)author of 200 peer reviewed papers with a H-factor of 44. He lectured in several courses on chemical and reactor engineering and is co-author of the book Chemical Process Technology (2nd edition).

reactors are operated at high chain growth probability conditions at which heavy paraffinic hydrocarbons (wax) are produced with high selectivities. Waxes are subsequently fed to hydrocrackers and converted to the desired cut of the barrel.¹ Lower hydrocarbon chain growths are expected in processes based on high-temperature Fischer–Tropsch (HTFT) for gasoline production.² Nevertheless, hydrocarbon conversion reactions, including hydroisomerization, are required to upgrade the octane number of the FTS-based gasoline.

Practical feasibility of the conventional GTL should benefit from the so-called ‘economy of scale’.³ However, process intensification is essential to make use of feedstocks with limited and scattered availability (e.g., renewables) or associated petroleum gas on offshore platforms. The current importance of intensified GTL technologies is illustrated by the number of academic research groups and companies such as CompactGTL,⁴ Velocys,⁵ and Chevron,⁶ currently involved in this research. Yet, it should be stressed that efforts to develop intensified GTL processes do not necessarily aim to substitute the state of the art, already optimized for large scale applications, but are responses to the availability of alternative feedstocks.

From the catalysis engineering prospect, running several reactions by coupling two or more functionalities in a single catalyst particle is a well-known and attractive approach, such as in hydroisomerization. First examples describing the incorporation of additional functionalities in FTS, including water–gas-shift (WGS) and acidity,⁷ have been reported more than two decades ago.^{8–10} The former is intrinsically present in Fe-based FTS catalysts or alternatively can be introduced by addition of a dedicated component such as Cu-based WGS catalysts.¹⁰ If H₂/CO ratio is smaller than the reaction stoichiometry (i.e., H₂/CO = 2), a high CO conversion may only be achieved in combination with a reasonable extent of *in situ*

WGS. On the other hand, intraparticle H₂/CO ratios stay closer to the optimal stoichiometric value by feeding H₂ deficient syngas, due to the higher diffusivity of H₂.¹¹ Therefore, WGS functionality is of high importance, especially when coal or biomass are used as syngas sources with H₂/CO ratios around unity.¹²

Other active sites have been introduced to add acid functionality to the catalyst. This aims to couple FTS to either etherification¹³ or acid-catalyzed hydrocarbon upgrading (*via* (hydro)cracking, (hydro)isomerization, *etc.*). The latter is the subject of this report. While almost a century of literature is available on FTS catalysts, still no new reviews update the recent advances and findings on this topic.^{12,14–20} This contribution is confined to the recent open literature on zeolite-based bifunctional catalyst systems. The possible acid-catalyzed reactions that are likely to occur under FTS conditions are discussed first and their feasibility is assessed (section 2). Following, the possible side reactions at the metal sites, resulting from their interaction with the zeolite, are addressed. These side reactions are consequences of the combination of functionalities, which may affect or alter the product distribution (section 3). On these grounds, the combination of FTS and acid functionalities and their cooperative catalytic performances are discussed in detail as a function of the proximity between both phases, namely on the reactor, catalyst particle, and active phase levels (section 4).

2. Relevant acid/zeolite catalyzed reactions

The idea behind the combination of FTS and acid functionalities is the direct production of liquid hydrocarbons from syngas *via* consecutive CO polymerization and hydrocracking.

Freerk Kapteijn

Freerk Kapteijn (1952), MSc in Chemistry and Mathematics, received his PhD on ‘Metathesis of alkenes’ in 1980 at the University of Amsterdam. After post-doc positions (Coal Science) in Amsterdam and Nancy (ENSIC), he became Associate Professor in Amsterdam. Moved to Delft University of Technology in 1993, received a personal professorship in 1999, and since 2008 he has been section leader of Catalysis Engineering, with visiting professorships at ETH Zürich, Tianjin and Zhejiang Normal University. His research interest focuses on the interplay of catalysis and engineering, comprising structured and multifunctional catalysts, adsorption, separation and (catalytic) membranes. He has co-authored over 400 publications in peer-reviewed journals and book chapters.

In this section, the feasibility of hydrocracking and other acid-catalyzed reactions, likely to occur over bifunctional catalysts, under FTS conditions is discussed.

2.1. Hydrocracking

Hydrocracking, catalytic cracking, and thermal cracking are the most important types of cracking. The former two proceed in the presence of a solid catalyst and their main difference is H₂ co-feed in the case of hydrocracking. Fluidized catalytic cracking or FCC is a well-known cracking process where no H₂ is co-fed to the reactor, operated at 753–823 K. One of the most important components of FCC catalysts is an acidic zeolite. Hydrocrackers on the other hand, are operated in the temperature range of 623–713 K.² At such lower temperatures, incorporation of a (de)hydrogenation function into the catalyst formulation, besides the acidity, is the key to enhance catalyst activity and stability. Conventionally, the (de)hydrogenation function is introduced by a metal, supported on the solid acid catalyst (Table 1).

Hydrocracking catalysts are similar to those of hydroisomerization in the sense that they both contain (de)hydrogenation and acid functionalities. This is due to the fact that reaction intermediates are similar in both reactions: the formation of cracked products is preceded by an isomerization step (see below).

The hydrocracking reaction mechanism is schematically illustrated in Fig. 1 for a representative hydrocarbon. The reaction is initiated by formation of a carbocation. In case of olefins, the carbocation can readily be formed *via* addition of a proton, supplied by Brønsted acid sites. Otherwise, in the case of saturated hydrocarbons, a dehydrogenation step should precede. Alternatively the olefin may form by abstraction of a hydride ion from the hydrocarbon. The hydride ion can be accepted by the acid catalyst and be combined with a proton to form molecular H₂.²¹

Before C–C scission, the carbocation undergoes skeletal isomerization to form an iso-carbocation.

This proceeds through a secondary carbocation rearrangement, most probably *via* a protonated dialkylcyclopropane (Fig. 1) for hydrocarbons containing five or more carbon atoms. For C₄ hydrocarbons, formation of protonated dialkylcyclopropane is energetically unfavorable since it would call for a primary carbocation as intermediate.²³

The next mechanistic step of hydrocracking is scission of the C–C bond at the β position of the positively charged carbon atom (β-scission) to form a lighter alkene and a lighter carbocation. The latter may go through a further sequence of reactions as described above or it may be converted to an alkene upon proton abstraction by the acid catalyst. Finally, the olefinic products may adsorb on a metal site and become hydrogenated.

Table 1 Various (de)hydrogenation and acid functions of hydrocracking catalysts. Adapted from ref. 22

	Hydrogenation function (metal)	Acid function (support)	
Increasing hydrogenation	Ni/Mo Ni/W Pt/Pd	Al ₂ O ₃ Al ₂ O ₃ /halogen SiO ₂ /Al ₂ O ₃ Zeolites	Increasing acidity
	Low sulfur conditions		

Fig. 1 Hydrocracking reaction mechanism for a representative hydrocarbon.

Fig. 2 Examples of different types of β -scission, imposed to different carbocation intermediates. n : carbon number.

Five types of β -scission can be distinguished with respect to the stability of the carbocations involved (Fig. 2) for which the relative reaction rates obey the following order: $A \gg B1 \approx B2 > C \gg D$.²⁴ A 'fast' hydrocracking occurs once the hydrocarbon has been hydroisomerized and subsequent branching in the chain leads to fastest hydrocracking. Among the different acid supports employed in hydrocracking catalysts (Table 1), zeolites offer a high stability as well as shape selectivity. Inside shape selective zeolites such as ZSM-5, the branched reaction intermediates are blocked where they undergo successive isomerization steps and rapid cracking.²⁵

The above-mentioned reaction steps for hydrocracking are based on a monomolecular mechanism. In the so-called bimolecular mechanism,^{26–28} an alkene is protonated by the Brønsted acid and forms a dimer with another olefinic hydrocarbon (Fig. 3). This oligomerization process may continue and depending on the position of the double bond and the positively charged carbon on the chain, branched carbocations may be produced. The carbocations may further return a proton to the acid catalyst to form an olefin (which is larger than the starting molecules) or they may crack. The bimolecular mechanism seems more feasible than the protonated cyclopropane formation for hydroisomerization and/or hydrocracking of small hydrocarbons (such as C4) that would require primary carbocation intermediates through the latter route.^{29,30}

In the absence of a (de)hydrogenation functionality (such as in FCC catalysts), hydrogen is transferred from the hydrocarbon feed to the catalyst surface and distributed over the adsorbed hydrocarbon species. This enriches the H/C ratio of a fraction of components (usually the lighter ones) while

reducing that of the others (usually the heavier ones) and thus carbon is rejected in the form of coke on the catalyst surface.³¹ In this case, pentacoordinated structures (Fig. 4) are formed by direct protonation of the paraffins which can crack in α position of the positively charged carbon (α -scission, protolysis). Once significant concentrations of alkenes are created, cracking through the aforementioned mechanism(s) and β -scission may follow. Products of α -scission include those that require primary carbocation intermediates if to be formed *via* β -scission.³²

Technology selection for FTS product upgrading *via* cracking is based on the following considerations: FTS hydrocarbons are in principle hydrogen rich. Therefore, a carbon rejection strategy such as that in FCC is not essential, although applicable.^{33,34} In addition, the absence of contaminants like sulfur in FTS wax allows cracking under mild conditions and high partial pressures of hydrogen are not necessary (see below), thus hydrogen addition to the process would not become costly. On these grounds, hydrocrackers are the standard units for conversion of LTFT heavy

Fig. 4 Catalytic cracking by protonation of an alkane to form a pentacoordinated carbocation followed by α -scission (protolysis). Adapted from ref. 2.

Fig. 3 Dimerization of a carbenium ion and an alkene.

hydrocarbons to liquid fuels.¹ Both process and catalysts involved are designed as such to be selective to the target hydrocarbon range (conventionally to middle distillates) and minimize over-cracking of the desired products. Further, they are optimized for production of branched hydrocarbons to improve the cold flow properties in case of diesel or octane number for gasoline-range hydrocarbons.³⁵

As compared with the refinery hydrocrackers, these units are operated at much milder conditions in terms of temperature, pressure, and H₂/feed ratio in the case of FTS wax hydrocracking. This is due to the high reactivity of heavy paraffinic molecules in hydrocracking, plus the absence of strong catalyst poisons, such as sulfur and nitrogen containing compounds, in FTS wax. The involved catalysts are typically less acidic as well.³⁶

A bifunctional FTS catalyst should be capable of catalyzing hydrocracking along with FTS at the process conditions of the latter. Although this is limited to speculation in many related reports, there are crystal clear indications that H-ZSM-5 satisfies this objective for the cracking functionality.^{37–44}

In model reactions, Martinez *et al.*³⁸ showed that *n*-hexadecane conversion drops rapidly from 80% to zero over H-ZSM-5 (Si/Al = 15) in 1 h, regardless of co-feeding H₂. However, a stable conversion level of 80% was measured once the same H-ZSM-5 was physically mixed with equal mass of Co/SiO₂. Since hardly any C1 was found in the reaction products, this stability improvement was attributed to the (de)hydrogenation activity of Co. In fact, reduced (non-sulfided) Co-containing catalysts have been explored for FTS wax hydrocracking elsewhere.⁴⁵

A challenge that the hydrocracking component has to deal with under FTS reaction conditions is the presence of CO and H₂O. While the former may disturb the (de)hydrogenation functionality, H₂O affects the acid-catalyzed reactions. Although stable, *n*-C16 conversion over H-ZSM-5 halved upon H₂O addition to the feed stream.³⁸ The negative effect of CO and H₂O addition on *n*-dodecane hydroconversion was demonstrated over Ni/H-ZSM-5 (Si/Al = 66) extrudates (including Al₂O₃ as binder).⁴¹ The choice of Ni as the (de)hydrogenation function was on the basis that it is less sensitive than Pt to the presence of CO. An almost 80% *n*-C12 conversion drops to *ca.* 5% at 493 K after CO and H₂O are co-fed in order to simulate an FTS environment. However, the conversion level can be increased to *ca.* 80% by raising the reaction temperature to 533 K. This *n*-C12 conversion was reasonably stable up to 70 h on-stream.

Since unsaturated hydrocarbons (mainly α -olefins) are FTS primary products, they can be protonated directly by the acid catalyst even in absence of a (de)hydrogenation function. This is confirmed by results obtained in bifunctional reaction systems consisting of a catalyst bed of acid zeolite downstream that of an FTS catalyst bed (see section 4.1). Sartipi *et al.*⁴⁷ observed C7–C9 hydrocarbon formation along with C3–C5 during C6 hydroconversion over a mesoporous H-ZSM-5 catalyst at FTS process conditions. This observation points at the importance of the bimolecular mechanism

during bifunctional FTS, as also suggested by others.⁹ C6 conversion considerably increases from 4 to 96% over mesoporous H-ZSM-5 (Si/Al \approx 40) by switching the reactant from *n*-hexane to 1-hexene (Fig. 6).⁴⁶ Addition of a hydrogenation metal to the acid component in this case enhances the formations of isoparaffins.^{40,48,49}

It is noteworthy that no C1 was observed in the product spectrum of mono-functional H-ZSM-5 catalysts. This result excludes the protolysis mechanism (α -scission) and rules out the acid-catalyzed reactions as origin of methane production during bifunctional FTS. A Co-containing catalyst may produce significant amounts of C1 through hydrocarbon hydrogenolysis (see Fig. 6 and section 3.2) while the selectivity to this product is low over Pt-containing hydrocracking catalysts (see Fig. 5).

Among zeolites H-ZSM-5 (Si/Al \approx 16), H-Beta (Si/Al \approx 13), and H-Y (Si/Al \approx 3), the first one shows the highest activity in *n*-C6 cracking followed by H-Beta and H-Y. The latter displayed the highest selectivity to C6 isomers.³⁷ A more recent study⁴³ demonstrates that only strong acid sites, active for hydrocracking at the operating temperature window of cobalt-based FTS catalysts, give rise to deviations from a conventional ASF product distribution (see also section 4.2).

2.2. Other acid-catalyzed reactions of importance under FTS conditions

Besides hydrocracking, an acidic zeolite may catalyze other reactions, including (but not limited to) hydroisomerization, oligomerization, aromatization, alcohol dehydration, *etc.* As explained in section 2.1, hydroisomerization and oligomerization intermediates are already involved in the hydrocracking mechanism. Thus, products of both reactions are expected during bifunctional FTS. Hydrocarbons up to C13 are formed through oligomerization reactions from a mixture of ethene and propene over Pt/H-ZSM-5 and Pt/H-Beta, regardless of

Fig. 5 Product distribution of *n*-hexadecane hydrocracking over Pt containing H-ZSM-5 (Si/Al \approx 16) extrudates (including Al₂O₃ as binder) at different temperatures. In addition to *n*-C16 ($SV_{n-C16} = 0.08\text{--}0.1\text{ h}^{-1}$), the feed included H₂O ($SV_{H_2O} = 0.25\text{--}0.3\text{ h}^{-1}$) and syngas with the composition N₂:H₂:CO = 50:33:16 ($GHSV_{gas} = 3600\text{--}3800\text{ l l}_{cat}^{-1}\text{ h}^{-1}$). *n*-C16 conversion is 33%, 83%, and 100% at 503 K, 523 K, and 538 K, respectively.³⁷ Reproduced with permission from Elsevier.

Fig. 6 Conversion and product selectivities in C6 hydroconversion over a mesoporous H-ZSM-5 (mesoH-ZSM-5) and 20 wt% Co-0.3 wt% Ru/mesoH-ZSM-5. Data were collected after 20 h on-stream at 513 K, 15 bar total pressure, $H_2/C_6 = 9.0$, $N_2/H_2 = 2.0$, and $SV = 13 \text{ mol}_{C_6} \text{ kg}_{\text{cat}}^{-1} \text{ h}^{-1}$. Either *n*-hexane or 1-hexene was used, as indicated in the legend.⁴⁶ Note that hydrocarbons larger than C6 were also formed over mesoH-ZSM-5 which were not specified. Reproduced with permission from Wiley-VCH Verlag GmbH & Co.

syngas addition. The major products are mono-branched hydrocarbons in C5–C9 range while Pt/H-ZSM-5 is more active than Pt/H-Beta.⁴⁰ The significant oligomerization activity of H-ZSM-5 reduces the production of lower olefins when this zeolite is added to the FTS catalyst, whereas this effect is less for H-Beta and H-MOR⁵⁰ and is not observed for mixtures containing MCM-22, ITQ-2, and ITQ-22.⁵¹ The C2–C4 range olefin to paraffin ratio decreases with a decrease in Si/Al ratio of H-ZSM-5, when physically mixed with a Fe-based FTS catalyst,⁵² which further highlights the occurrence of olefin oligomerization over this zeolite in bifunctional FTS.

In principle, zeolites having more acid sites of medium strength show higher isomerization activity, whereas stronger acid sites catalyze cracking.² In line with this general statement, mesoporous H-ZSM-5 (Si/Al ≈ 40) was compared with H-ITQ-2 (Si/Al ≈ 40) and mesoporous H-USY (Si/Al ≈ 40) for the effect of their acid strength and density on catalytic performance.⁴³ While the former shows activity in *n*-C6 hydrocracking, H-ITQ-2, having even a higher density of weaker acid sites, catalyzes only the isomerization reaction and mesoporous H-USY was inactive under the applied process conditions. Both mesoporous H-ZSM-5 and H-ITQ-2 supported Co-catalysts yield a similar ratio of *iso*- to *n*-C4 in FTS, but the former is considerably more selective to the C5–C11 fraction due to cracking of large FTS hydrocarbons, resulting in a non-ASF product distribution (Fig. 7). Further comparing the product slate of Co supported on the three above-mentioned zeolites, revealed that hydrocarbon isomerization alone is not enough to lead to non-ASF catalytic behavior.⁴³ It was concluded that an outstanding isomerization activity might only decrease the chain growth probability (Fig. 7), since branched hydrocarbons may not participate in chain propagation as effectively as linear ones.

Fig. 7 Molar fractional distribution of FTS products after 140 h on-stream at 513 K, 15 bar total pressure, feed composition $H_2/CO = 1$, and $GHSV = 12 \text{ m}_{\text{STP}}^3 \text{ kg}_{\text{cat}}^{-1} \text{ h}^{-1}$. Co/mesoH-ZSM-5: mesoporous H-ZSM-5-supported Co; Co/mesoH-USY: mesoporous H-USY-supported Co. Co loadings are about 20 wt%.⁴³ Reproduced with permission from Wiley-VCH Verlag GmbH & Co.

At low temperatures, hydrocracking catalysts effectively catalyze the hydroisomerization reaction. The extent of hydrocracking relative to hydroisomerization can be tuned by adapting the process conditions, acid strength, and the ratio between metal and acid sites in a catalyst. At temperatures below 523 K, hydroisomerization of 1-octene over Pt/H-ZSM-5 (Si/Al = 32) dominates over hydrocracking in the presence of CO. The contrary holds at higher temperatures and/or in absence of CO.⁴⁰ Process temperatures of LTFT favor hydroisomerization and oligomerization rather than hydrocracking over H-ZSM-5 catalysts. Oligomerization of lower olefins followed by the limited growth of branched hydrocarbons (that are produced by hydroisomerization, oligomerization, and hydrocracking) effectively stops the chain propagation at around C10 while the large hydrocarbons are very reactive to hydrocracking.⁵³ This may explain why most of the reported bifunctional catalysts, operated at LTFT conditions, are selective towards gasoline-range hydrocarbons rather than the diesel range (which is the desired product of the conventional two-steps LTFT and hydrocracking process).

On the other hand, HTFT conditions are typically associated with low chain growth probabilities and target gasoline-range hydrocarbons, lower olefins, and oxygenates. Consistent results show that FTS oxygenates are dehydrated by zeolites in bifunctional systems.^{54–56} As long as liquid fuels are targeted, HTFT is followed by isomerization and reforming units to improve the octane number of the produced gasoline. Bifunctional catalysts that contain zeolites are reported to produce notable amounts of aromatic compounds^{51,57–59} and olefins, which essentially can improve the octane number. However, a high production of aromatics may result in severe deactivation of the acid catalyst (see section 5). Formation of aromatics may become smaller at lower operating temperatures.⁴⁶

3. Side reactions at the metal sites

The main function of metal sites with respect to the present application is FTS, *i.e.*, chain propagation (*e.g.*, *via* CO

insertion) and hydrogenation. In the current context, FTS performance in combination with acid functionality is included in section 4, while two important side reactions are described in this part.

3.1. Hydrogenation

Co⁰ is the FTS active phase in Co-based catalysts whereas carbides form over Fe⁰ in an early stage of the FTS reaction or during the catalyst activation by means of CO. These carbon containing species are believed to effectively catalyze FTS rather than metallic Fe.⁶⁰ In parallel, hydrogenation is anticipated over both Co- and Fe-based catalysts. In addition to saturation of olefinic hydrocarbons, this reaction directly converts CO into methane. Fig. 8 shows that, as compared with a Fe-catalyst and in spite of a lower reaction temperature, the methane level is higher than what is anticipated by extrapolating the ASF distribution to $n = 1$ over a Co-catalyst. This is due to the higher hydrogenation activity of Co in comparison with Fe, which makes this side reaction more important over the former. Therefore, Co FTS catalysts are known to be more sensitive than Fe-based catalysts to changes in H₂ concentration and/or process temperature.^{61,62}

De Jong *et al.*⁶³ showed that methane selectivity through CO hydrogenation sharply increases as Co particle size becomes smaller than 6–10 nm, while for larger sizes the reaction is not structure sensitive. The density of lower index surface crystallographic planes or steps and corners increases as particle size decreases.⁶⁴ The higher methane selectivity of small particles is mainly brought about by their higher hydrogen coverage⁶⁵ and the high activity of low coordination sites, residing at corners and edges.⁶⁶

As compared with conventional catalysts, more heterogeneous Co sites are found when supported on a zeolite *via* impregnation.^{44,46} For example, infrared (IR) spectra of pre-adsorbed CO (Fig. 9) show that low frequency bands at 1988–2020 cm⁻¹ are clearly detected over an H-ZSM-5-supported

Co while these bands are less pronounced over Co/SiO₂. Such IR bands are assigned to linearly adsorbed CO on Co⁰ centers of lower coordination that are more located on open low-index surface crystallographic planes or steps and corners.^{67–69} Therefore, direct CO hydrogenation (CO + 3H₂ → CH₄ + H₂O) partly explains the relatively high methane production over zeolite-supported Co-catalysts (even in the absence of Brønsted acidity) and can be rationalized on the basis of the strong metal–support interaction on the structured aluminosilicate.^{44,46}

Due to their lower intrinsic activity, relatively high reaction temperatures are employed for Fe-base catalysts even in LTFT applications. Higher reaction temperatures will lead to a decrease in FTS chain growth probability and thus higher production of methane through FTS. In spite of this, the C1 selectivity is almost similar over both SiO₂ and zeolite-supported Fe-catalysts.⁷⁰ In some occasions, it is claimed that H-ZSM-5 would even enhance the formation of the active carbide phase and improve the catalyst performance.⁷¹

3.2. Hydrogenolysis

Other than hydrogenation, a hydrocarbon may undergo many types of reactions over metals, namely hydrogenolysis,

Fig. 8 Molar fractional distribution of FTS products over 20 wt% Co/SiO₂ and a bulk Fe-catalyst after 5 h on-stream. Experiments were performed at 15 bar total pressure, feed composition H₂/CO = 1513 K and 523 K for Co/SiO₂ and bulk Fe, respectively, $GHSV/m_{STP}^3 \text{ kg}_{cat}^{-1} \text{ h}^{-1} = 12$ and 24 for Co/SiO₂ and bulk Fe, respectively.

Fig. 9 IR spectra of pre-adsorbed CO on Co/SiO₂ (bottom data set) and mesoporous H-ZSM-5-supported Co (Co/mesoH-ZSM-5, top data set). In each data set, the temperature is increased in a DRIFTS cell to 373, 423, 473, and 513 K, respectively, according to the arrows. Co loadings are about 10 wt%.

isomerization, dehydrocyclization, and aromatization.⁷² Except for hydrogenolysis, most of these reactions do not occur in the FTS reaction environment as evidenced by negligible presence of branched, cyclic, and aromatic hydrocarbons in conventional FTS products. It should be noted that in bifunctional catalysts, some of the above-mentioned reactions become important over acid sites, as already discussed in section 2.

Hydrogenolysis is an exothermal reaction, catalyzed by group VIII metals (including Ru, Co, Fe, and Ni). This reaction proceeds *via* formation of adsorbed hydrocarbon radicals as reaction intermediates followed by C–C scission. In contrast to hydrocracking, the adsorbed radical intermediate mechanism results in low isomerization activity and therefore unbranched products.⁴⁵

Different mechanisms have been proposed for hydrogenolysis of saturated hydrocarbons. In all cases the reaction is initiated by dehydrogenative chemisorption of the hydrocarbon.^{73,74} As first example, ethane hydrogenolysis proceeds *via* 1,2-adsorbed intermediates followed by a series of elementary steps that lead to formation of hydrogen deficient surface species.⁷⁵

C–C scission results from the reaction between the adsorbed intermediate and H₂, being the rate determining step.⁷³ As the ratio of dehydrogenation-to-hydrogenolysis activity of a metal increases, lower *x* values (reaction (1)) are expected. Thus, values of 4 and 2 are reported for Co and Ni, respectively.⁷⁶ It is noteworthy that H₂ pressure has a strong inverse effect on the reaction rates over most group VIII metals except for Fe and Re. This has been explained by a decrease in the concentration of C₂H_{*x*}(ads) with increasing H₂ pressure.⁷³ The specific activity of group VIII metals for ethane hydrogenolysis follows the following order:⁷⁷ Os > Ru > Ni > Rh > Ir > Re > Co > Fe > Cu > Pt ≈ Pd, while for propane Co shows a higher activity than Ni.⁷⁸

The rate of hydrogenolysis increases with the carbon number of alkanes which is attributed to lower average dissociation energies of C–C bonds in larger molecules.⁷⁹ As an example, *n*-heptane hydrogenolysis is several orders of magnitude faster than that of ethane at 478 K.⁷⁶

Alternatively, Anderson and Avery proposed 1,3-adsorbed intermediates for isomerization and hydrogenolysis of simple aliphatic hydrocarbons larger than C₂. In this scheme, one carbon atom is doubly bonded to a surface metal atom (Fig. 10).⁸⁰ If the C–metal double bond is located primarily at the terminal C atom, and assuming that the C–C bond adjacent to the C–metal double bond cracks preferentially, then methane will be the main product of hydrogenolysis.

The distribution of primary hydrogenolysis products depends on the metal. On Ni, the reaction scheme involves successive demethylation at terminal C–C bonds of the

Fig. 10 Structure of adsorbed *n*-heptane intermediates formed on metals.⁷⁹

hydrocarbon chain which lead to formation of C1 fragments that are hydrogenated to form methane.^{45,81} This scheme also applies reasonably well to Co, but not to Fe.⁸¹ This explains the significant amounts of C1 and C₂, reported over hydrocracking catalysts that contain Ni or Co as the (de)hydrogenation function.³⁵

In contrast, a nonselective rupture of different C–C bonds is reported over Pt-containing catalysts. For *n*-heptane, hydrogenolysis was the predominant reaction on all the metals of group VIII except Pt, on which extensive isomerization and dehydrocyclization were also observed.⁸² The lower hydrogenolysis activity of noble metals, as compared with very active hydrogenation metals such as Ni, makes them the preferred choice for (de)hydrogenation functionality when employed in hydrocracking and hydroisomerization catalysts.

Some reports speculate that hydrogenolysis may add to methane production over bifunctional FTS catalysts.^{9,44,77} Related literature on this aspect is not clear and even controversial in some occasions. *n*-hexadecane hardly showed any conversion over Co/SiO₂ at 523 K (H₂/*n*-C16 = 2.9, N₂/*n*-C16 = 4.4).³⁸ In another study however, *ca.* 25% *n*-hexane conversion is reported over Co/SiO₂ at 493 K where C1 was dominantly produced (H₂/*n*-C6 = 9.0, N₂/*n*-C6 = 2.0).⁴⁴ Under similar conditions, Co/H-ZSM-5 was more than 50% selective towards methane while no C1 was detected over H-ZSM-5. The *n*-C6 conversion over Co/H-ZSM-5 and H-ZSM-5 was 94 and 13%, respectively.⁴⁴ Accordingly, zeolite-supported Co-catalysts that contain a large fraction of coordinatively unsaturated Co sites are more active than Co/SiO₂ in *n*-C6 hydrogenolysis.^{44,46} This reaction is known to be structure sensitive and TOFs often vary with particle size. Nevertheless, there is no consistency in literature on the type of such dependence.⁸³ In any case due to competitive CO adsorption under FTS reaction conditions, hydrogenolysis is not expected to occur to such an extent as in the absence of CO. Including propane in a syngas feed did not significantly change the methane selectivity, and ethylene and propylene addition even reduced this value,⁷⁷ probably due to reinsertion and scavenging of C1 surface species. Further investigations, *e.g.*, *via* labeling the reactant molecules, are required in order to (completely) unveil the extent of hydrocarbon hydrogenolysis as side reaction during FTS.

4. Zeolite-containing FTS systems

From the perspective of Catalysis Engineering,⁸⁴ three different process levels can be distinguished in bifunctional FTS catalysts based on the state and extent of the contact between the acidic and FTS function: the reactor level, the catalyst

particle level and the catalyst active phase level. These three levels are thoroughly discussed in this section.

4.1. Reactor level

Two different configurations can be distinguished in literature for combination of zeolites and FTS metals (Co and Fe) at the reactor level: separate or dual layer beds, containing the zeolite downstream of the FTS catalyst (denoted as '2BED'), and single mixed beds containing a homogeneous physical mixture of the two catalysts (denoted as '1BED') (Fig. 11). Both catalyst beds can be operated at a similar temperature, which is in the limit of either LTFT or HTFT conditions. Applications with a higher temperature at the zeolite bed region, closer to that of hydrocrackers, or even dual reactor systems have also been reported.^{85,86} Such layouts resemble the two step processes (such as in the Shell SMDS¹) and are not discussed in this context. 1BED systems may be considered as at the border between the reactor and catalyst particle levels and their related discussions are divided between sections 4.1 and 4.2.

Both Fe- and Co-based FTS have been studied in the two above-mentioned configurations (2BED and 1BED). Severe alkali migration from the alkali-promoted Fe-containing catalysts to H-ZSM-5 is reported for 1BED during the course of reaction.^{57,59} As a result, a decline in FTS activity⁵⁹ and a considerable selectivity shift towards lower value light paraffins (including C1)⁵⁷ make the 1BED configuration less attractive than the 2BED. In contrast, higher CO conversions and C5–C11 selectivity were obtained in 1BED when a La-promoted Fe was studied.⁵⁵

The improved performance of 1BED over 2BED systems in terms of increased selectivities to gasoline-range hydrocarbons is in line with results reported for Co-based catalysts.^{40,41,54} Schaub *et al.*^{40,41} reveal that under the applied process conditions, the C10–C20 molar fraction may be larger in the 2BED configuration than in the 1BED, while both systems represent similar fractions of liquid hydrocarbons (C5–C20).⁴⁰ In any case, the 1BED operation leads to more branched hydrocarbons,^{40,41,54} pointing to an enhanced contribution of acid-catalyzed reactions in the latter.

Fig. 11 Schematic representation of different configurations that zeolite and FTS phases may have with respect to one another in bifunctional systems. From left to right: separate or dual layer beds, containing the zeolite downstream the FTS catalyst (2BED), single mixed bed containing a homogeneous physical mixture of the zeolite and FTS catalyst particles (1BED), coating layer of the zeolite over FTS catalyst (COAT), and FTS active phase supported on the zeolite (SUPP).

Many reports indicate that the C1 selectivity increases as the bed configuration changes from 2BED to 1BED^{9,40,41,55,77} and various reasons, including acid cracking, hydrocarbon hydrogenolysis, heat effects, *etc.* are hypothesized as possible origins. FTS is highly exothermic and heat effects are typically eliminated by diluting the catalyst bed with an inert and/or recycle of liquid product. However, some acid zeolite catalyzed reactions, including hydrocracking, as well as possible hydrocarbon hydrogenolysis over metal sites are also exothermic and may add to the produced heat. The C1 selectivity was reduced by half upon adding an inert solid to a physical mixture of Co/SiO₂ and H-ZSM-5 while it did not change in the absence of the zeolite. Furthermore, less aromatics were detected in the liquid products after dilution.⁷⁷ These results indicate that heat effects are even more important in bifunctional systems, especially in 1BED configuration. In more recent studies, zeolites H-USY, H-Beta, H-MOR, and H-ZSM-5 that were mixed with Co/SiO₂ and diluted with SiC in a 1BED configuration, did not lead to additional C1 at all.^{38,87} This observation suggests that reactions over the acid zeolites do not produce additional methane.

4.2. Catalyst particle and active phase levels

1BED systems may also consist of catalyst particles that are homogeneous mixtures of zeolite and FTS phases (Fig. 11). A closer contact (than that in the 1BED configuration) between the FTS and zeolite functionalities is possible if a coating layer of the latter is put over the FTS active phase^{88–90} (denoted as ‘COAT’). As schematically shown in Fig. 11, the zeolite layer may coat the catalyst particle (*i.e.*, coating of μm sized particles) or the FTS metal agglomerates (*i.e.*, coating of nm sized particles). The contact can be further maximized by dispersing the FTS metal particles in a zeolitic support^{42,47,89,91} (denoted as ‘SUPP’).

For Fe-based catalysts it is shown that SUPP⁹² and COAT^{71,93} systems are more selective than 1BED to the C5–C11 fraction. Accordingly, an intimate contact between the two components is a key to the bifunctional performance of these hybrid catalysts. A systematic study on Co-catalysts revealed that upon changing the system configuration from 1BED to COAT and further to SUPP (Fig. 11), deviations from a classical ASF product distribution become more pronounced (Fig. 12).⁸⁹ This practical observation is an evidence of the above statement about the necessity of the close proximity of the two types of active sites.

The COAT configuration concept may be termed ‘core-shell’ as described by Tsubaki *et al.*^{94,95} for FTS reaction in analogy to earlier studies for other reactions.^{96,97} In an ideal core-shell scenario, a defect free reactive zeolite membrane should cover a core of FTS catalyst. A critical review of the relatively large number of reports on this topic,^{49,71,88,90,93–95,98–110} points to the challenge of making and characterizing such catalytic membrane reactor on the level of catalyst particles (*i.e.*, coating of μm sized particles) *via* the hydrothermal synthesis approach:⁸⁹ exposing a Co/SiO₂ core to a hydrothermal

Fig. 12 Fractional molar distribution of FTS products after 20 h on-stream at 513 K, 15 bar total pressure, feed composition H₂/CO = 2, and GHSV = 2.4 m_{STP}³ kg_{cat}⁻¹ h⁻¹. Co/mesoH-ZSM-5: mesoporous H-ZSM-5-supported Co. Co loadings are about 10 wt%.⁸⁹ Reproduced with permission from Elsevier.

environment in the presence of zeolite structure directing agent, brings about partial transformation of the SiO₂ into zeolite where Co agglomerates are wrapped (*i.e.*, coating of nm sized particles). In other words, the supported Co-catalyst functions as a synthesis precursor during the hydrothermal approach rather than as an ideal catalyst core.⁸⁸ Regardless of the necessity for in depth characterization, good selectivity data to gasoline-range hydrocarbons and/or isoparaffins are reported for both Fe- and Co-based COAT systems^{71,98,105} along with too high C1 selectivity. At the same time, Co-based coated catalysts exhibit lower CO conversion levels than the conventional base catalysts^{88,89,94,95,98–110} due to mass transport limitations.⁸⁹ Unfortunately, the majority of the FTS reactions catalyzed by coated catalysts are reported at very high conversion levels of the limiting reactants (*e.g.*, >90% CO conversion at H₂/CO ratio of 2 (ref. 49, 90, 93)) which is not desired for activity evaluations.¹¹¹ Since FTS catalysts in general are not highly productive, a loss in activity should be considered as a significant obstacle for practical applications. One report claims that an intimate contact with H-ZSM-5 promotes the formation of an active carbide phase in Fe-containing catalysts and hence, enhances the catalyst activity:⁷¹ the authors report a 90% CO conversion for H-ZSM-5-coated Fe-catalyst after *ca.* 150 h on-stream which is *ca.* 30% higher than that over the uncoated sample. However, since this reaction was performed at H₂/CO ratio of 1 (which is half of the stoichiometric value of 2), products associated with *ca.* 15% of the converted CO are not clearly stated (olefin/paraffin ratio of 0.9 and 17% carbon selectivity to CO₂ are reported).

Alternatively, the cooperative action of FTS and acid sites can be enhanced by employing the acidic zeolite as FTS catalyst support (SUPP, Fig. 11). However, such an application is restricted by the limited external surface area of zeolites. Dispersion of metals in the zeolite micropores reduces their FTS

activity and selectivity for the following reasons: (i) due to stronger metal-support interactions, metal reducibility decreases considerably inside the zeolite structure,^{46,112} (ii) even on inert carriers, it is well-known that Co particles smaller than 6–10 nm in size are not optimal for FTS (section 3.1),^{63,65} and (iii) mass transport limitations in the very narrow zeolite micropores may severely alter the local H₂/CO ratio with respect to that in the bulk and also lead to over-exposure of the hydrocarbon products to acid sites.^{42,47} To address these drawbacks mesopores were created in crystallites of different zeolites *via* desilication¹¹³ and the resulting hierarchical zeolites were employed as support for Co^{43,44,46,47,89} and Ru.^{42,91} For 3 wt% Ru-catalysts supported on ZSM-5 and Beta, product selectivity correlates with the extent of support mesoporosity: upon increasing the NaOH concentration (employed desilicating agent) and thus creating more mesoporosity, the selectivity to methane decreases (over the prospect catalyst) while that to gasoline-range hydrocarbons increases.^{42,91} This has been attributed to reduced diffusion limitations, which eliminate the over-exposure of the FTS hydrocarbons to strong acid sites and keep the local H₂/CO ratio inside the catalyst particle closer to bulk conditions.^{42,47} Nevertheless, very high concentrations of NaOH results in excessive zeolite amorphization and lowers the C5–C11 selectivity by reducing the acid-catalyzed reaction. Therefore, synthesis optimization of mesoporous zeolites should be realized specifically for FTS catalyst applications. In a series of reports by Sartipi *et al.*,^{43,44,46,47,89} synthesis optimization of mesoporous H-ZSM-5 (denoted as ‘*mesoH-ZSM-5*’) involved demetalation *via* subsequent base and acid treatments. NaOH (alkaline) and tetrapropylammonium hydroxide (TPAOH, organic) bases were employed as desilicating agents. Under similar treatment conditions, NaOH results in a more severe desilication than TPAOH,⁴⁷ creating mesostructures with pore sizes and volumes very similar to the amorphous SiO₂ reference support.^{44,47} A more controlled desilication with TPAOH gives rise to more mesoporosity suggesting a higher degree of hierarchy with large cavities communicated with smaller mesopores.^{46,47} Further, TPAOH is preferred over NaOH, since Na⁺ is a well-known poison for Co-based FTS catalysts and trace amounts results in a lower FTS activity as compared with the organic treated samples.⁴⁷

The consecutive acid treatment (with HNO₃) removes the produced extraframework aluminum, caused by zeolite desilication, and boosts the FTS activity. Moreover, the acid treatment increases the Brønsted acidity of *mesoH-ZSM-5*.⁴⁴

The large mesopore surface area of *mesoH-ZSM-5* improves the metal dispersion at elevated Co loadings. The *Co/mesoH-ZSM-5* catalyst is much more active than *Co/H-ZSM-5* and the conventional *Co/SiO₂*.^{44,89} Moreover, the time-on-stream stability of *Co/mesoH-ZSM-5* and *Co/SiO₂* is comparable, in terms of CO conversion, during 140 h^{43,46} (insert in Fig. 13a). The high selectivity to liquid hydrocarbons over H-ZSM-5-supported catalysts is visible as a cutoff in the molar distribution above C11 in terms of the ASF distribution of

conventional catalysts (*e.g.*, *Co/SiO₂*, Fig. 7 and 12). Measurements after 140 h on-stream shows that *Co/mesoH-ZSM-5* is *ca.* three times more selective than *Co/SiO₂* towards C5–C11 cut, producing a large fraction of unsaturated hydrocarbons, other than α -olefins. Moreover, wax production is considerably suppressed over the zeolite-containing catalyst⁴⁶ (Fig. 13).

5. Stability of zeolites in view of bifunctional FTS applications

One of the major concerns regarding industrial applications of zeolite-containing bifunctional catalysts is the stability and lifetime of the acid component with respect to that of the FTS. In this view, coke formation is a main parameter, since deposition of coke would eventually deactivate the acid

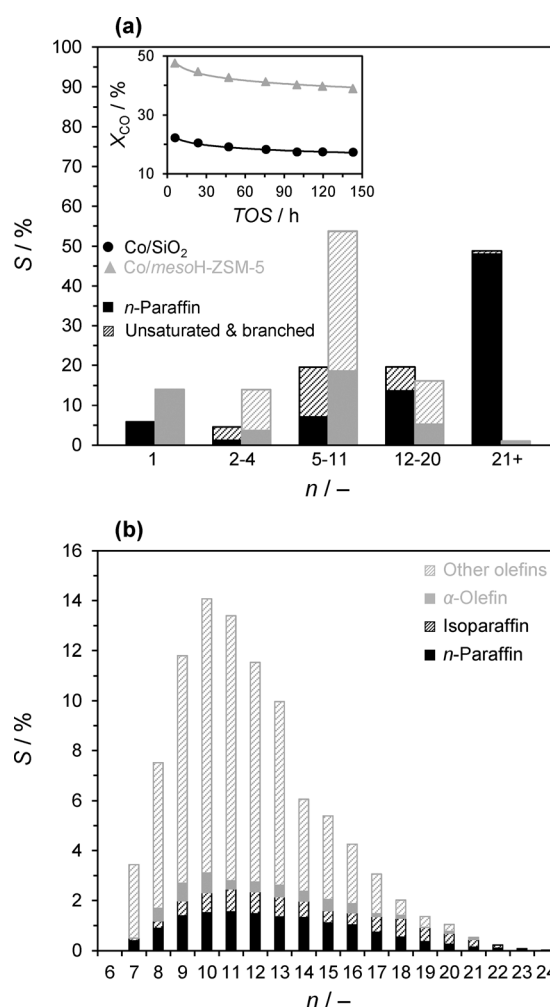

Fig. 13 (a) Carbon selectivity of FTS products after 140 h on-stream. In each carbon number group from left to right: *Co/SiO₂* and *Co/mesoH-ZSM-5*. ■: *n*-paraffins; ▨: sum of isoparaffins and olefins. Insert shows the time-on-stream (TOS) evolution of the CO conversion. (b) Selectivity distribution of liquid hydrocarbons, produced over *Co/mesoH-ZSM-5* as collected after 140 h on-stream. FTS experiments were performed at 513 K, 15 bar total pressure, feed composition H₂/CO = 1, and GHSV = 12 m_{STP}³ kg_{cat}⁻¹ h⁻¹. Co loadings are about 20 wt %.⁴⁶ Reproduced with permission from Wiley-VCH Verlag GmbH & Co.

functionality and, consequently, alter the product selectivity.³⁸ This parameter correlates with the extent of aromatic formation in the course of reaction. Botes *et al.*^{57,58} compared two H-ZSM-5 zeolites with different Si/Al ratios (15 and 140) when combined with Fe-based catalysts in 1BED and 2BED configurations. Although initially higher, the aromatic fraction produced over the high-acidity zeolite sharply decreased and dropped below that produced over the low-acidity one. Therefore, the low-acidity zeolite showed a more stable behavior and produced a higher fraction of aromatics after 150 h TOS. This conclusion on H-ZSM-5 is confirmed by others as well.^{52,92} In general H-ZSM-5 is fairly resistant towards coke formation due to its narrow channel type structure and well distributed acid sites. FTS reaction results confirm that H-ZSM-5-containing 1BED systems are more stable and selective to branched hydrocarbons than mixed catalysts containing other zeolite topologies including MCM-22, ITQ-2, ITQ-22, IM-5, USY, H-Beta, and H-MOR.^{38,51,87} The lifetime can considerably be improved by decreasing the zeolite crystallite size, allowing a better utilization of the zeolite microporosity, due to shorter diffusion distances. Another approach frequently reported is adding Pd as a (de)hydrogenation function.^{51,52,92}

Up to 250 h on-stream at 553 K, the isomer selectivity drops by less than 25% of its corresponding value at 50 h TOS over H-ZSM-5 (Si/Al = 140).⁹² However, the decrease in production of C4 isomers is more than 50% of its initial value after *ca.* 200 h on-stream at 573 K (H-ZSM-5, Si/Al = 25).⁵⁶ FTS rate was relatively stable over the Fe component under these conditions. Reactivation at 573 K in an O₂ containing environment is not sufficient to regenerate the H-ZSM-5 zeolite (Si/Al = 14) while the Fe component is totally reactivated after reduction.¹¹⁴ As expected, coke formation is amplified over the zeolite at HTFT conditions, where the reaction temperatures are higher than 573 K. On the other hand, many reports suggest a more stable performance of the acid function at LTFT conditions.^{6,41,46,98,103,107} Recently, a 7.5 wt% Co–0.2 wt% Ru-catalyst, supported on alumina bound ZSM-5, is reported to show a stable performance and high selectivity to C5–C20 up to 1500 h on-stream at 493 K.⁶ After 140 h on-stream at 513 K, reactivation of Co/*meso*H-ZSM-5 by H₂ at 773 K results in the recovery of the initial *iso*- to *n*-C4 product ratio over this catalyst along with its initial FTS activity.⁴⁶ This suggests that H-ZSM-5 framework does not collapse under LTFT conditions, although lowered intensity of MFI diffraction patterns are reported for spent catalysts as compared with the fresh ones.⁵⁰

6. Conclusions

The combination of zeolites with an active FTS phase increases the product selectivity towards liquid hydrocarbons. This approach offers a great potential for intensified and direct production of synthetic fuels from syngas. Among different zeolite topologies, the most promising results are obtained with H-ZSM-5. The main advantages of the use of

this zeolite in combination with FTS functionalities are: (i) it is one of the few zeolites industrially produced and applied for acid-catalyzed hydrocarbon conversion reactions, (ii) it has a (relatively) stable catalytic performance, especially at LTFT process conditions, and (iii) besides acid-catalyzed cracking, it has a fair isomerization and oligomerization activity at low temperatures. The latter oligomerization initiates the hydrocracking reaction *via* a bimolecular mechanism, since olefins are primary FTS products.

Although HTFT conditions are, in principle, more compatible with hydrocracking and other acid-catalyzed reactions than LTFT conditions, acid sites deactivate relatively fast due to coke formation during HTFT. Therefore, such an integration of different functions seems to be more feasible at LTFT conditions, making Co the desired FTS phase.

In most literature examples, the combination of Co based FTS catalyst and zeolitic acidity results in high selectivities towards gasoline range hydrocarbons. This is mostly due to the type and mechanisms of acid-catalyzed reactions over zeolites in bifunctional systems (Fig. 14). While oligomerization decreases the amount of lower olefins, cracking of the reactive large hydrocarbons breaks the conventional ASF product selectivity at higher carbon numbers. Both reactions will produce branched hydrocarbons. Small branched hydrocarbons do not participate in the FTS chain propagation effectively and, at the same time, larger hydrocarbons will be get trapped in the narrow zeolite channels (such as those of H-ZSM-5) where they undergo excessive isomerization and cracking. In this sense, the use of larger pore zeolites, acidic enough as to display cracking activity under FTS conditions, would be ideal for the production of longer hydrocarbons, in the diesel fuel range.

A crucial factor affecting the product selectivity of bifunctional catalysts is the proximity between acid and FTS components. The closer the sites the more olefinic products reach acid sites before undergoing hydrogenation. This fact makes zeolite supported Co catalysts the best performing ones among the different options in terms of active site proximity. However, in spite of these advantages, a number of drawbacks need to be addressed in order to make the direct synthesis of liquid hydrocarbons from syngas more attractive, namely:

(i) the high selectivity towards methane derived from the strong interactions between the FTS phase and the zeolite. This is a great catalyst synthesis challenge related to the state of the FTS metal particles, since reducibility, size, interactions with the zeolite, coordination of metal atoms, *etc.* directly affects the FTS chain growth. In many occasions, approaches including hydrothermal synthesis to form a zeolite coating around the metal (agglomerates) or impregnation of the FTS functionality with zeolitic supports, led to lower chain growth probabilities and/or promotion of side reactions (*e.g.*, CO hydrogenation and hydrocarbon hydrogenolysis).

(ii) the long-term stability of these catalysts has been largely unexplored. Future studies should certainly address this point and demonstrate that the lifetime of the

Fig. 14 Schematic representation of reactions involved in zeolite-containing FTS catalysts.

zeolite containing catalysts is comparable to that of other FTS catalysts.
