Towards low-cost, environmentally friendly printed chalcopyrite and kesterite solar cells

Cite this: *Energy Environ. Sci.*, 2014, 7, 1829

Hamed Azimi,^{*a} Yi Hou^{ac} and Christoph J. Brabec^{ab}

Solution-processed organic and inorganic semiconductors offer a promising path towards low-cost mass production of solar cells. Among the various material systems, solution processing of multicomponent inorganic semiconductors offers considerable promise due to their excellent electronic properties and superior photo- and thermal stability. This review surveys the recent developments of "all solution-processed" copper–indium (–gallium)-chalcogenide (CuInS_2 , CuInSe_2 and $\text{Cu}(\text{In, Ga})(\text{Se, S})_2$) chalcopyrites and copper–zinc–tin-chalcogenide ($\text{Cu}_2\text{ZnSnS}_4$ and $\text{Cu}_2\text{ZnSnSe}_4$ (CZTS(e))) kesterite solar cells. A brief overview further addresses some of the most critical material aspects and associated loss mechanisms in chalcopyrite and kesterite devices. Today's state-of-the-art performance as well as future challenges to achieve low-cost and environmentally friendly production is discussed.

Broader context

Photovoltaics as the only truly portable renewable-energy conversion technology available today demonstrate strong commercial growth and hold promise for significant market opportunities. Among various solar cell technologies, thin-film technologies are one of the cost-competitive solar technologies due to reduced material and fabrication costs. However, the production of thin film solar cells typically relies on capex intense vacuum-based techniques, and/or high-temperature processes, both increasing manufacturing costs. Solution processing of multicomponent inorganic solar cells is considered as a promising alternative fabrication route to the conventional high cost vacuum techniques.

1. Introduction

Thin film solar cell technology has a major potential for further cost reductions, provided that the expected increases in production facility size and efficiency are realized.^{1–3} Fig. 1 compares the world record single cell efficiencies of various types of thin film solar cell technologies including organic, inorganic and hybrid semiconducting materials. Among the various types of thin-film solar cells, $\text{Cu}(\text{In, Ga})(\text{Se, S})_2$ (CIGS_{Se}) is today the combination that delivers one of the highest power conversion efficiencies. The CIGS_{Se} world record efficiency above 20% was only recently demonstrated,^{4,5} and highlighted how close CIGS_{Se} already is to poly-Si technology. Although CIGS_{Se} technology has a number of attractive features, the deposition of the absorber layer is a complex process requiring vacuum technologies. The common approach for the production of copper indium gallium diselenide (CIGSe) solar cells is currently based on the co-

evaporation of individual metallic elements or on sputtering of the suitable metal precursors followed by a crystallization step at high temperature in the presence of Se vapor and/or hydrogen selenide gas (known as deposition-reaction or a sequential process). These processes are generally challenging due to the difficulty to control the film composition over a large area and the use of toxic gases for selenization. Over the past few years, the quest for low cost production focused more and more towards the non-vacuum deposition methods. The non-vacuum approaches for deposition of multicomponent inorganic absorber layers can be generally summarized under three main categories: (i) solution deposition based on electrochemical and chemical bath-based techniques like electrodeposition, electroplating and chemical bath deposition (CBD). (ii) Printing/coating from molecular-based precursor solutions. (iii) Printing/coating from particulate-based solutions. Electrodeposition is one of the well-established electrochemical techniques in the electronics industry.⁶ However in this method, the deposition of multicomponent semiconductors like CIGSe is generally a complex process as the different elements have different redox potentials and reduction kinetics.^{7,8} Multistep deposition might be necessary to provide a good control of stoichiometry and phase homogeneity. Among the approaches mentioned, the particulate- and precursor-based approaches have recently received a great deal of attention due to their potential to simplify the fabrication processing for large-scale manufacturing.

In this article, our main focus is dedicated to the solution-processed fabrication of chalcopyrite CuInS_2 (CIS), CuInSe_2 (CISE) and $\text{Cu(In, Ga)(Se, S)}_2$ (CIGSSe) solar cells, addressing all the various methods like molecular, and particulate-based solutions as well as their hybrid combinations. Furthermore, as an important alternative to the CIGSSe technology, we also review the current state-of-the-art fabrication routes for solution processed kesterite $\text{Cu}_2\text{ZnSnS}_4$ (CZTS), $\text{Cu}_2\text{ZnSnSe}_4$ (CZTSe), and $\text{Cu}_2\text{ZnSn(S,Se)}_4$ (CZTSSe) solar cells.

2. Fundamental aspects of chalcopyrite and kesterite solar cells

2.1. Device concept

Fig. 2 shows a classical configuration of CIGSe and CZTSe solar cells, which is based on a heterojunction cell structure. The absorber layer with a thickness of typically 1–2 μm is deposited

on molybdenum-coated soda-lime glass substrates. The heterojunction is then formed by the deposition of an n-type buffer layer (usually 50 nm CdS layer deposited by chemical bath deposition), the sputtering deposition of an intrinsic i-ZnO (typically with a thickness of 40–70 nm) and eventually of a transparent conductive oxide layer as the window layer (normally a heavily doped ZnO:Al or an indium-doped tin oxide (ITO) layer). A schematic band diagram of a CIGSe solar cell under zero-bias voltage condition is shown in Fig. 2. Some of the most critical recombination paths governing the diode current of such a solar cell structure are: recombination at the absorber surface, in the absorber bulk, at the absorber back contact, and in the absorber space charge region (SCR). The high probability for the charge carrier recombination at the absorber surface is one of the main disadvantages of such a cell structure; the advantage however is a negligible recombination in the buffer and window layer due to the large bandgap recombination in those regions. The high recombination at the heterojunction can be circumvented to a large extent by the proper design of the band diagram.¹⁰ The highly doped CdS layer with a large bandgap of 2.4 eV is being typically used as an n-type layer in junction with a p-type CIGS or CZTS absorber layer in order to reduce the collection losses due to surface recombination (SR) of carriers photogenerated by short wavelength light and to transport electrons from the junction to the front surface. The recombination in the quasi-neutral region (QNR) largely depends on the bandgap gradients. The opportune bandgap gradient in chalcopyrite and kesterite solar cells can be achieved by controlled incorporation of Ga or S. Some examples of bandgap grading for solution processed chalcopyrite and kesterite solar cells are given in the following sections. The poor collection of carriers photogenerated at the back contact can be improved by enhancing the electron diffusion length (L_n). A longer L_n can be achieved by passivating the interfaces, or increasing the crystallite size.¹¹

Hamed Azimi received his MEng in Electrical Engineering from Ferdowsi University of Mashhad, Iran. In December 2006, he joined Konarka Austria to study for a PhD under the supervision of Prof. Christoph. J. Brabec (Konarka) and Prof. Kurt Hingerl (Johannes Kepler University Linz, Austria). He obtained his PhD in Engineering Sciences in 2011. Since 2011, he has been a post-doctoral fellow in the group of

Prof. Brabec in the institute of Materials for Electronics and Energy Technology (i-MEET) at the Friedrich Alexander University Erlangen-Nürnberg, where he leads the group of solution processed inorganic and hybrid semiconductors for photovoltaic application.

Yi Hou is currently a PhD student under the supervision of Prof. Christoph J. Brabec at the institute of Materials for Electronics and Energy Technology (i-MEET) at Friedrich Alexander University Erlangen-Nürnberg (FAU). He received his MEng degree in Materials Science and Engineering from Beijing University of Chemical Technology (2012). He was awarded the Erlangen Graduate School in

Advanced Optical Technologies (SAOT) award in 2013. His research interest includes low-temperature solution processed inorganic and hybrid semiconductors and their applications in photovoltaics.

Christoph J. Brabec is holding the chair "Materials for Electronics and Energy Technology (i-MEET)" at the materials science department of the Friedrich Alexander University Erlangen-Nürnberg. Further, he is the scientific director of the Erlangen division of the Bavarian Research Institute for Renewable Energy (ZAE Bayern, Erlangen), board member of the ZAE Bavaria and board member

of the Energy Campus Nurnberg. Before joining the university, he was in SIEMENS research labs as the project leader for organic semiconductor devices and in Konarka Technologies Inc. as CTO. He is author and co-author of more than 200 papers and nearly 100 patents and patent applications.

2.2. Grain boundaries and defects

In polycrystalline solar cells, the size of grains and the recombination velocity at the grain boundaries (GBs) are the key parameters to determine the rate of the charge carrier recombination. One primary influence of the GBs is the interruption of the long-range order in the crystal. A simple relationship between the effective diffusion length (L_{eff}) for a polycrystalline material and a monocrystalline material can be defined as

$$L_{\text{eff}}^{\text{poly}} = \left[(L_{\text{eff}}^{\text{mono}})^{-2} + 2S_g / (D_n g) \right]^{-1/2}, \quad (1)$$

where S_g stands for the recombination velocity at the grain boundaries of grains with the size g and D_n is the diffusion coefficient for electrons.¹³ The GBs play an important role in controlling the current voltage characteristic of solar cells. The GBs may adversely influence the majority carrier mobility, therefore enhancing the series resistance. Also, the lifetime of the minority carriers can be reduced by increasing minority carrier recombination at GBs.¹¹ The GBs can even exhibit a recombination higher than in the bulk and additionally they

may become charged to induce band bending.¹⁰ For examples, in high efficiency record CIGSSe devices, the loss in the open circuit voltage (V_{oc}) is attributed to the electrostatic potential variations at charged extended defects like GBs.¹⁴ There is however consensus that the GBs in chalcopyrites have more benign effects compared to other semiconductor materials.¹⁵ The less negative influence of GBs is explained by multiple factors such as the inherently low GB recombination in CIGS, the beneficial effects of O and Na in the passivation of GBs and the reported downshift of the valence-band energy at GBs that effectively repels holes from the GB region.^{13,16–18} The latter case is well attributed to the formation of a Cu-poor ordered defect compound (ODC) at the CIGS surface.^{19,16} The effect of GBs is shown to be similarly benign in kesterites. However, studies showed that due to the constituent atoms at the GBs, more defect levels in the energy gap of CZTS bulk crystals can be found compared to CIGSe, which, in turn, enhance the probability of recombination of the photogenerated charge carriers.²⁰

With respect to the different loss mechanisms discussed, it is important to understand the formation of the various defects

and secondary phases in chalcopyrites and kesterites. Defects may appear as single defect states with well defined energy levels within the bandgap or as multiple defect states and defect distributions with a quasi continuous state density in the bandgap.¹⁰ In CIGSSe, the first-principle investigation showed that the indium-on-copper-antisites (In_{Cu}) and the copper vacancy (V_{Cu}) are, respectively, the dominant donor and acceptor defects.^{21,22} The acceptor defect V_{Cu} is found to have a shallow ionization energy level and lower formation energy than the donor defects as In_{Cu} (Ga_{Cu}) and Cu_i , explaining therefore the intrinsic p-type conductivity and also the difficulty in the control of n-type doping in this material. Furthermore in ternary chalcopyrites, due to the energetically favorable donor-acceptor compensation between V_{Cu} and In_{Cu} , there is a high probability of formation of defect clusters like $[2V_{\text{Cu}} + \text{In}_{\text{Cu}}]$ and even the ordered defect compound such as CuIn_5Se_8 .²³ In CZTS, V_{Cu} has similarly a low formation energy and becomes dominant in the case of Cu-poor and Zn-rich samples. Moreover, the cause of frequently observed non-stoichiometric kesterite samples can be explained on grounds of a strong tendency towards formation of self-compensated defect clusters, like $[V_{\text{Cu}} + \text{Zn}_{\text{Cu}}]$, $[\text{Zn}_{\text{Sn}} + 2\text{Zn}_{\text{Cu}}]$ and $[2\text{Cu}_{\text{Zn}} + \text{Sn}_{\text{Zn}}]$ ^{23,24} (see Table 1 for a comparison between the dominant defects in chalcopyrites and kesterites).

For solution processed solar cells, the effects of grain boundaries and the defects can be very different from the devices fabricated based on the conventional vacuum deposition routes. The defect chemistry and the mechanisms of phase transformation can vary markedly depending on the initial solution precursors and the temperature used for the film deposition and the phase transformation. The losses induced by the smaller size of grains and the possible impurities from the precursors may exert a profound impact on the final device performance. To date, there have been very limited studies to provide in-depth insights into the properties and the loss mechanisms of solution processed chalcopyrite and kesterite devices. Fundamental insights using advanced characterization methods are still necessary to overcome the limitations in these devices.

2.3. Characterizations

Raman spectroscopy, X-ray diffraction, energy-/wavelength dispersive X-ray spectroscopy and X-ray fluorescence are

commonly being used to obtain information on crystalline quality, phase purity and chemical composition. Among the techniques mentioned above, Raman spectroscopy is an extremely useful technique that provides insight into the lattice strains and the existence and spatial distribution of different phases. Furthermore, in the preparation of molecular precursor solutions, Raman measurements can be used to analyze the degree of intermixing between the precursor components.²⁵ In CISSe samples, Raman spectroscopy can be used to distinguish the desired stable chalcopyrite (CH) from the metastable copper-gold CuAu (CA) and the metastable copper rich $\text{CuIn}_5(\text{S}, \text{Se})_8$ structure.^{26–29} For CZTS samples, while the coexistence of CZTS, Cu_2SnS_3 (CTS), and ZnS may not be distinguishable by diffraction techniques, Raman analysis is able to detect and distinguish between these phases through their characteristic scattering peaks.^{30–33} The employment of Raman spectroscopy at resonance conditions is shown to be essential for the distinction between the secondary phases in kesterites.³⁴ For a detailed overview on assignment of Raman peaks to different binary and ternary secondary phases related to the CZTS system, see ref. 30 and 34. To monitor the phase formation/transition during the thermal annealing, *in situ* techniques and thermal analyses like thermogravimetric analysis and differential thermal analysis are being implemented.^{35–38}

To obtain information about the defect physics and their relationship to the device performance, characterization tools such as photoluminescence (PL),^{39–41} admittance spectroscopy, deep level transient spectroscopy (DLTS)^{42–44} and Hall measurements^{45,46} are relevant. A combination of these techniques is generally necessary to analyze the shallow, mid-bandgap as well as the deep defects; while admittance measurements generally provide information on the deep defects, information on the density and the energy of shallow defects can be obtained by Hall and PL measurements.¹⁵ In PL, studying the excitation intensity and the temperature dependence of the emission peaks sheds light onto the activation energies of the defects as well as the nature of the associated transitions.^{22,46} At low temperatures and low excitation intensities, the PL spectrum can be dominated by the band-tail (BT) recombination. The BT recombination is the emission band that follows the band edge potential fluctuations originating from the local deviations in the distribution of donor and acceptor states (see Fig. 3). For instance, comparing the defect

properties of Cu-poor chalcopyrite and kesterite samples, a recent study found the higher probability of nonradiative recombination for the latter system. This conclusion was drawn on the basis of two observations: (1) the lower PL intensity and (2) the significantly high excitation densities needed for transition from a band-tail (BT) to a band-to-band (BB) recombination in CZTS. This result is consistent with the fact that kesterite has greater tendency towards formation of point defects with associated electronic states near the midgap.²²

Another important method associated with PL spectroscopy is the time-resolved photoluminescence (TR-PL). TR-PL is used to directly measure the minority carrier lifetime in CIGSe and CZTS solar devices.^{47,48} The low minority carrier lifetime can result in higher dark current (J_0) and can therefore promote the V_{oc} deficit in solar cell devices (eqn (2)).

$$V_{oc} = \frac{KT}{q} \ln\left(\frac{J_{sc}}{J_0} + 1\right), \quad (2)$$

Fig. 4 shows a TR-PL data of a 15.2% efficient hydrazine-based CIGSe solar cell.⁴⁹ A lifetime of $\tau = 5.4 \pm 0.2$ ns was measured for this cell which is found to be lower than the lifetimes measured for high-performance vacuum-processed CIGSe solar cells (>10 ns).⁴⁸

To investigate the influence of GBs and their passivation on the performance of chalcopyrite and kesterite-based solar cells, scanning probe microscopy methods like scanning Kelvin probe microscopy (SKPM) and conductive probe atomic force microscopy (CP-AFM) are frequently used.^{50,51} The simultaneous measurement of the surface film topography along with probing the variations of electrostatic surface potential (SKPM) and the current flow/surface conductivity (CP-AFM) at GBs documents important information with relevance to solar cell operation. High-resolution mapping can help in understanding whether the device performance is limited by grain bulk, grain surface, and/or GBs. A recent study,⁵⁰ comparing the surface potential maps of CIGSe, CZTS, and CZTSSe, showed similarly for all the samples higher positive surface potentials at the GBs compared to the surface of the grains. This observation suggests that in

Fig. 4 Time-resolved photoluminescence (TR-PL) trace measured for the hydrazine-processed CIGSe with a PCE of 15.2%. Inset: the PL spectrum and the extracted lifetime in the vicinity of the band edge emission. Reprinted with permission from ref. 49, Copyright 2013, John Wiley & Sons, Ltd.

kesterites like CIGSe, GBs assist in the collection of minority carriers into the GBs. CP-AFM measurements were further used to demonstrate that there is no significant minority carrier recombination at GBs and the process of minority carrier collection by the GBs indeed occurs.

Besides the methods discussed above, a wide variety of other microscopic and spectroscopic techniques are available to study the electrical, optical, structural as well as the device properties of thin film solar cells (for a detailed overview, see ref. 52 and 53).

3. Solution processed chalcopyrite solar cells

3.1. Deposition from molecular-based precursor solution

A solution based on a mixture of different molecular precursors can be directly used to produce films with a desired stoichiometric ratio of elements, high crystallinity and good uniformity in composition.⁵⁴ Chemical modifiers and sacrificial ligands are generally required to control the reaction kinetics and the solubility of precursor materials. Thermal treatment is being performed to convert the precursors into the desired phase and to remove the residual organic species. The concentration and the viscosity of the precursor solution are crucial factors impacting film formation and drying kinetics. Furthermore, the quality of the final metal chalcogenide film can be strongly influenced by the bulkiness and volatility of the sacrificial ligands. Small ligands are being preferred to avoid the formation of cracks and disruption of films during thermal decomposition.⁵⁵ Heat treatment at high temperatures in a sulphur or selenium atmosphere typically is necessary in order to complete the phase transformation and to minimize the porosity of the film.⁵⁶

3.1.1. Deposition from hydrazinium precursors. The solution processability of metal chalcogenides is being limited by the presence of strong covalent bonds that result in poor

solubility in most solvents. A process known as dimensional reduction was successfully applied to overcome this limitation.⁵⁷ In this approach, addition of a strong ionic reagent breaks up the poorly soluble metal-anion framework. Sufficient incorporation of ionic reagents reduces the dimensionality of the framework substantially leading to the formation of oligomeric and monomeric components. The precursor solution containing metal chalcogenide anions reduced by cationic species is then used for film deposition. In the final step, the precursor film is being decomposed and transformed into the desired metal chalcogenide film upon heat treatment.⁵⁷ Hydrazine proved to be an excellent reducing agent for dissolving many different metal chalcogenides; it tends to strongly coordinate and has a small size and high vapor pressure that allows formation of the desired product with minimum impurities at relatively low temperatures. In recent years, this strategy was well established to fabricate high efficiency chalcopyrite (CIGSSe) and kesterite (CZTSSe) solar cells. Various metal sulfides and selenides, *e.g.* Cu_2S , In_2Se_3 , SnSe , ZnS , were efficiently dissolved in hydrazine to form soluble precursors. The disruption of the chalcogen framework in hydrazine was further significantly promoted by introducing elemental S and Se atoms.^{58,59} Various deposition methods like spin-coating were applied to achieve the desired film thickness. After each deposition, an intermediate annealing step at $250\text{ }^\circ\text{C} \leq T \leq 350\text{ }^\circ\text{C}$ is necessary to eliminate hydrazine and the extra S/Se. The final step requires annealing at temperatures above $500\text{ }^\circ\text{C}$ to promote grain growth and densification.^{60,61} Mitzi *et al.*^{57,60,62} developed the fabrication of CIGSSe solar cells using a hydrazine solution process, and reported recently a PCE of 15.2%,⁴⁹ which is one of the highest published device efficiencies among all solution-processed solar cells.

Despite the obvious superior performance of hydrazine-processed devices, the application of this process is limited by the toxicity and high reactivity of hydrazine. Recently, Zhou *et al.*⁶³ reported the use of non-hydrazine solutions for processing of $\text{CuIn}(\text{S,Se})_2$ (CISSe) solar cells from hydrazinium precursors. The hydrazinium precursors were prepared by dissolving copper sulfide (Cu_2S) and indium selenide (In_2Se_3) precursors in hydrazine. The Cu-In hydrazinium precursors were found to be fairly soluble in a mixture of ethanolamine (EA) and dimethyl sulfoxide (DMSO). The solubility in the EA/

DMSO mixture is described by the reducing capability of EA and the tendency of the S atom in DMSO to coordinate with metal cores. The scheme in Fig. 5 illustrates the dissolution process for Cu-In hydrazinium into a solvent combination of EA/DMSO, where excessive S/Se is being added to accelerate the dissolution of precursors. The performance of solar cells fabricated by this approach was limited by the device thickness due to the lower degree of crystallinity and smaller grain size of films compared to the films from a pure hydrazine-based approach. Optimized CISSe solar cells fabricated using this method showed a device efficiency of 3.8% for an absorber film thickness of 300 nm, which is comparable to the hydrazine-based CISSe solar cells with a similar film thickness. Despite the apparent attractiveness, this technique still has the disadvantage of using hydrazine for preparation of initial precursors, which limits the applicability of the process.

3.1.2. Non-hydrazine processing. To evade the use of hydrazine, less toxic and environmentally benign solvents were employed to fabricate different chalcopyrite solar cells. A green formulation has been proposed based on the dissolution of different metal-nitrates and metal-halides in an alcoholic solvent.⁶⁴ Doctor blading a precursor paste prepared by dissolving an appropriate molar ratio of copper nitrate hemipentahydrate, indium chloride and gallium nitrate hydrate in methanol and a subsequent gas-phase selenization step yielded CIGSSe solar cells with an efficiency of 6.7%. The viscosity of the precursor solution for doctor blading was adjusted by adding a proper amount of ethyl-cellulose (EC). Ahn *et al.*⁵⁴ used a similar route based on the precursor solutions of $\text{Cu}(\text{NO}_3)_2$ and InCl_3 dissolved in methanol to produce CuInSe_2 solar cells. The above synthesis route appeared to have the limitation induced by formation of a dense carbon layer between the absorber layer and the Mo back contact (Fig. 6). In an attempt to overcome this problem, the binder EC was replaced by polymethyl methacrylate (PMMA); although in this case no carbon-rich layer was observed, the performance of solar cells was limited by the film inhomogeneities and traces of parasitic oxide phases.⁶⁵ Following the approach described above, binder-free precursor solutions based on carboxylic chelate complexes and an alcoholic solvent have recently been used, leading to device efficiencies of up to 7.7%.⁶⁶ This process was based on an *in situ* oxidation of the organic solvent 1,2-propanediol and the coordination of carboxylic anions with metal species to form chelate complexes. Despite the efficiency improvement, the problem of a carbon-rich layer still remained due to the presence of carboxylate ligands. More recently, Park *et al.*⁶⁷ claimed almost carbon-free chalcopyrite CuInGaS_2 solar cells with PCEs of over 8% based on a direct coating of a solution comprised of the nitrate salts of Cu, In and Ga and the additive polyvinyl acetate (PVA) as an organic binder. The phase transformation of a precursor film to the final chalcopyrite film was performed through an oxidation step followed by a sulfurization heat treatment process; the temperature for annealing was selected in such a way that removes the remaining materials from the binder.

Based on an alcoholic solution, acetate salts of the metals, namely, copper(II) acetate and indium(III) acetate, were also

used to fabricate CIGSe solar cells.^{68,69} For incorporation of gallium, the chloride or acetylacetonate (acac) salts of gallium were used. It was shown that a sufficiently high partial pressure of Se improves the grain size and the overall degree of crystallinity during the selenization process. Fig. 7 compares the SEM images of CIGSe films prepared by using different Se pressures, where high Se vapor pressure led to enhanced grain size and low carbon contamination. Compared to the different metal salts/alcohol-based routes discussed so far, the deposition from the

acetate salts/alcohol based precursor solutions has the important advantage of the possibility to form absorber layers with minimum carbon-residues. This is well demonstrated by Ahn *et al.*,⁷⁰ combining metal acetate salts with a mixture of ethanol and ethanolamine to fabricate 7.7% efficient CuInSe₂ solar cells with significantly lower levels of carbon impurity. Notably, the deposited CuInSe₂ films showed a low carbon content of <5 at %, already by a simple pretreatment in air at a temperature of 300 °C.

Cui and his group⁷¹ introduced a process named as air stable ink rolling (AIR) to produce thin film CuInS₂ solar cells. This approach benefits from the use of rather low-cost precursors and an air-stable deposition method. The ink for CuInS₂ comprised of copper acetylacetonate (Cu(acac)₂), indium acetylacetonate (In(acac)₃) and elemental S dissolved in pyridine which is significantly less toxic compared to hydrazine. In this process, sulfur vulcanization with acetylacetonate provides the opportune viscosity and wetting properties for film processing. Films prepared by this approach were subsequently pre-baked at a temperature of 370 °C in air to burn off the organics and form a stack of Cu–In oxide layers. The precursor oxide films were then converted to CuInS₂ by a final sulfurization step in a bomb. The main deficiency of this approach was a poor control over the morphology and the film disruption induced during the sulfurization process resulting in solar cells with a low shunt resistance. Solar cells with PCEs of 2.15% were obtained after a post-KCN etching.

Apart from pyridine, other organic solvents with short ligands and strong coordinating properties were used to form an inexpensive and thermally degradable molecular precursor solution. For instance, a combination of butylamine and propionic acid was used to fabricate CuInS₂ nanocrystalline solar cells based on an *in situ* synthesis and film deposition route.⁷² The attractive aspects of this approach are the simplicity of the process as well as a relatively low sintering temperature (<300 °C) used for the fabrication of solar cells. The drawbacks to this approach are however the poor stability of the precursor solution and a disordered film morphology.²⁸ Fig. 8 shows a scanning electron microscopy (SEM) image of a CuInS₂

Fig. 8 (a) SEM top view image of a CuInS₂ NC film formed by an *in situ* deposition of precursor solution, sintered at a temperature of 270 °C. Reproduced with permission from ref. 28, Copyright 2013, Wiley VCH.

nanocrystal film prepared by the above approach. A detailed transport study of solar cells fabricated by this approach indicated a low carrier mobility of the CuInS₂ nanocrystal films, limiting the conversion efficiency to an absorber thickness smaller than 200 nm.²⁸ The use of an interpenetrating nanoscale heterojunction cell structure is expected to bypass the limitation of poor carrier collection at larger thicknesses.

Pan *et al.*⁷³ used a reaction of butylamine with carbon disulfide (CS₂) to synthesize butyldithiocarbamic acid (BDCA) that could efficiently dissolve a number of different metal oxides. Fig. 9 shows the reaction mechanism of butylamine with CS₂ and the following reaction with a metal oxide, forming different thermally degradable metal-organic molecular precursor solutions. Solar cells fabricated by the selenization of films processed from a butyldithiocarbamic acid-based ethanol solution showed PCEs exceeding 10%,⁷⁴ which are currently the highest reported performances for hydrazine-free molecular precursor-based CIGSe solar cells. Furthermore, the nontoxic ink formulation and the stability of the precursor solution over the course of months underscore the importance of the work reported by Pan *et al.*

Another common approach to fabricate chalcopyrite solar cells is based on the spray deposition technique. Typically, an aqueous precursor solution containing chloride metal salts along with thiourea as the sulfur source, in the case of CuInS₂,^{75–77} and selenourea as the Se source, in the case of CuInSe₂,^{78,79} has been used. The deposition temperature is typically around 250–400 °C, which is a lower temperature compared to the temperatures used for sulfurization or selenization. One attractive application of spray deposition is to allow fabrication of three-dimensional (3D) nanocomposite cell structures. Based on a chemical spray deposition and incorporating the CuInS₂ nanocrystals into the matrix of In₂S₃/nanocrystalline anatase TiO₂, Goossens *et al.*⁸⁰ reported solar cells with device efficiencies of about 5% (see Fig. 10).

A number of studies have reported the synthesis of single source organometallic precursors for deposition of ternary CuInS₂ and CuInSe₂ thin films.^{81–84} Hirpo *et al.*⁸¹ first described the synthesis of the compound (PPh₃)₂CuIn(SET)₄ to prepare the ternary CuInX₂ (X = S or Se) semiconductors. This compound comprises a copper(i) ion bound to two triphenylphosphine

ligands, an indium(III) ion with two terminal ethanethiolate ligands, and two ethanethiolate ligands coordinated between the metal centers.^{81,82} The solubility of this compound in common organic solvents and the low decomposition temperature (<250 °C) make it an attractive candidate for spray pyrolysis deposition.⁸¹ Banger *et al.*^{82–84} have further developed the synthesis and deposition of single source precursors for ternary CuInX₂ semiconductors. Also, solar cells with an efficiency of 6.7% were reported using the single-source precursor of

A brief summary of the reports discussed in this section, dealing with deposition from the molecular-based precursor solutions, is presented in Table 2.

3.2. Deposition from particulate-based solutions

In solution-based colloidal synthesis, it is possible to synthesize particles with a well-defined structure and high degree of purity. The nanoparticles offer a broad range of interesting tunable optical and electrical properties. Moreover, they offer excellent solution processing and their high reactivity is advantageous for phase transformation and film densification.^{86,87} In the synthesis of nanoparticles, it is very important to form particles with a uniform size and composition and with low levels of structural disorder. The use of organic ligands is generally required to properly control the kinetics of nucleation and growth during the synthesis. The organic ligands also play a key role in providing colloidal stability and later in assembling individual particles into a nanocrystal solid.⁸⁸ The common organic surfactants are the long chain alkyl ligands like trioctylphosphite and oleylamine.^{89–91} Due to the insulating properties of these ligands that hamper an efficient transport between the nanoparticles, a complete removal of the organic ligands is crucial. The need for removal of bulky organic ligands can however result in generation of cracks and discontinuities in the nanoparticle film and may leave behind unwanted carbonaceous impurities and surface defects.⁵⁵ To overcome the above issues, additional processing steps like ligand-exchange, heat treatment or chemical treatment are usually necessary.^{90,92–94}

In this section, we review the most recent work employing colloidal nanoparticle solutions for fabricating CIGS and

chalcopyrite-based thin film solar cells. Table 3 presents a summary of some selected results along with information for the corresponding device parameters and preparation details. The section is sub-categorized into the use of (a) single phase, (b) binary or multi-phase particles as starting precursors for the film deposition. The discussion on the chemistry and properties of inorganic nanoparticles is not the purpose of this review. For detailed information, the reader is urged to refer to the number of excellent reviews that comprehensively address the mechanism of growth and the properties of inorganic nanoparticles.^{95–97}

3.2.1. Ternary and quaternary phase nanoparticles.

Controlling the phase transition of a nanoparticulate film into a desired bulk composite is one of the most challenging aspects of device fabrication. This is particularly difficult when it comes to the direct use of pure ternary or quaternary nanoparticles. Despite many studies reporting the synthesis of single chalcopyrite CIS, CIGS and CIGSe particles,^{55,98–100} the direct use of them to fabricate efficient solar cell devices has rarely been reported. One problem is that single phase nanoparticles can be decomposed to different binary phases or to their pure metal constituents during the sintering process. Another difficulty is the frequently higher melting temperature of ternary or quaternary particles compared to their binary phase particles; this may hinder an effective sintering of nanoparticles during crystallization.

One of the first reports on the use of colloidal nanoparticles in solar cells was by Guo *et al.*,¹⁰¹ reporting solar cells with a PCE of 3.2% based on a CuInSe₂ nanoparticle ink. Oleylamine was used as the capping agent during the synthesis and nanoparticles were dispersed in toluene. The nanocrystals were successfully sintered to micrometer large crystalline grains

Table 3 Non-exhaustive survey of chalcopyrite solar cells fabricated based on deposition from the particulate-based solutions^a

Year	Absorber	J_{sc} (mA cm^{-2})	V_{oc} (mV)	FF (%)	PCE (%)	Deposition and solvent	Post-treatment	Description	Ref.
2008	CuInSe ₂	25.8	280	39	2.82	Drop-casting	450–550 °C (selenization in a Se/Ar atmosphere)	CuInSe ₂ NPs (CuCl, InCl ₃ and Se in OLA)	101
2009	Cu(In _{1-x} Ga _x)(S _{1-y} Se _y) ₂	23.7	455	51.5	5.5	Drop-casting, toluene	500 °C (selenization in a graphite box)	Cu(In _{1-x} Ga _x)S ₂ NPs (metal-chlorides and S in OLA)	90
2013	Cu(In,Ga)(S,Se) ₂	28.8	630	65.7	12	Doctor-blading, hexanethiol	500 °C (selenization in a graphite box)	Cu(In _{1-x} Ga _x)S ₂ NPs (metal(acac) salts and S in OLA)	102
2010	CuInSe ₂	16.3	410	46	3.1	Spray-coating	n.a.	CuInSe ₂ NPs (metal-chlorides and Se in a mixture of OLA and TBP)	104

through an annealing step at temperatures of 450–550 °C under Se vapor. To remove the organic capping molecules prior to selenization, films were annealed under a flow of argon gas at 500 °C. The selenization however caused the inclusions of void space in the absorber film, imposing a major constraint on the photovoltaic performance. One year later and based on the same synthesis approach, Guo *et al.* improved the efficiencies to over 5% using sulfur based nanoparticulate inks, *i.e.* CuInS₂ and Cu(In_{1-x}Ga_x)S₂ instead of CuInSe₂. This exchange significantly promoted the volume expansion during the selenization process and led to the formation of a denser absorber film (see Fig. 11).⁹⁰ Quaternary CIGS nanoparticles were designed instead of ternary sulfide and selenide nanoparticles to facilitate band-gap engineering. Most recently, hexanethiol based ink in combination with NaCl treatment yielded a 12% efficient

Cu(In,Ga)(S,Se)₂ nanocrystal-based solar cell.¹⁰² The positive influence of Na inclusion was attributed to an improved microstructure, substantially reducing recombination losses.

As mentioned above, post-thermal selenization poses additional costs and technological impediments on the production process. From this standpoint, it is important to highlight the work by Korgel *et al.*,¹⁰³ reporting colloidal CuInSe₂ nanoparticle based solar cells without high temperature sintering. By spray-depositing CISE and CIGSe nanoparticles and by optimizing the device structure, solar cells with PCEs of up to 3.1% were reported (see Fig. 12).^{104,105} In this study, the conventional Mo back contact was replaced by gold (Au) to ensure a good ohmic contact to the absorber layer. The general consensus is that a thin layer of MoSe₂, which is being formed during the crystallization process at high temperatures, subjects Mo to a selective electrical contact for CISE and CIGSe absorber layers.^{106,107}

The strategy to design new capping agents is an attractive way to improve the performance of nanocrystal-based solar cells without high temperature processing. All the experiments mentioned above have focused on the use of oleylamine as the capping agent. In attempting to improve the transport properties and functionality of nanoparticle based solar cells, different inorganic moieties including inorganic metal chalcogenide-hydrazinium complexes (MCC), S²⁻, HS⁻, and OH⁻ were adopted.⁸⁹ However, no improvement over the oleylamine-capped nanoparticles was found for MCC-capped CISE nanoparticles, which in addition had the drawback of using toxic and highly reactive hydrazine. The above study nevertheless showed that further studies on understanding and the engineering of novel ligands can facilitate low-temperature processed nanocrystal-based solar cells with high performance.

3.2.2. Binary and multinary phase nanoparticles. Different colloidal nanoparticle precursors including elemental metals, metallic alloys, binary metal chalcogenides and metal oxide nanoparticles can be used to form chalcopyrite thin films. A typically lower melting temperature (T_m) and higher reactivity of such nanoparticles as compared to the ternary or quaternary particles can ease the process of phase transformation and film densification. Studies on this approach were first focused on preparing powders of micro- and submicron-sized particles, and then dispersing them in a proper liquid media. Top-down techniques like milling and grinding techniques were often used for the particle size reduction.^{108–110} In one of the previous reports, Arita *et al.*¹⁰⁸ described the preparation of a screen

printing paste using ball-milled Cu, In and amorphous Se powders mixed with ethylene glycol monophenyl ether as the binding agent. The neat CuInSe_2 phase was formed after a sintering process at high temperatures of 700°C in a N_2 atmosphere. The process was further improved by coating intermetallic Cu–In particles with a subsequent selenization process. Basol *et al.*¹⁰⁹ and Norsworthy *et al.*¹¹¹ reported solar cells with efficiencies of up to 10% using sub-micron sized Cu–In alloy particles prepared by a melt atomization technique. The as-deposited precursor layers comprised of $\text{Cu}_{11}\text{In}_9$ and CuIn_2 particles were selenized in the presence of H_2Se to obtain a dense chalcopyrite CuInSe_2 film. Most recently, a process involving metallic particles of Cu, In and Ga in combination with subsequent selenization allowed the fabrication of $\text{CuIn}_{1-x}\text{Ga}_x\text{Se}_2$ devices with PCE of over 7%.¹¹²

As the line of research continued, a significant portion of the research was devoted to the preparation of particles *via* chemical means. Kapur *et al.*¹¹³ obtained high efficiency devices with PCEs exceeding 13% using a mixture of oxide based nanoparticles, which were reduced and selenized in H_2/N_2 and $\text{H}_2\text{Se}/\text{N}_2$ gas. The intermetallic Cu–In particles were also synthesized through a chemical reduction method.^{114–117} The inorganic compound sodium borohydride (NaBH_4) was commonly used as the reducing agent. NaBH_4 is a mild and inexpensive reagent whose reactivity is enhanced in the presence of certain organic and inorganic compounds.¹¹⁸ However, efforts to fabricate solar cells based on NaBH_4 -assisted chemical reduction led to fairly low efficiency devices ($\leq 1.4\%$). The problem was mainly related to the high level of porosity and structural free volume in the films.^{114,116} The breakthrough in this approach was reported by Kind *et al.*,⁸⁶ demonstrating 7% efficient solar cells based on the deposition of citrate-capped $\text{Cu}_{11}\text{In}_9$ nanoparticles, followed by selenization under H_2Se . The $\text{Cu}_{11}\text{In}_9$ particles with a diameter of 10–30 nm were prepared by a polyol-mediated synthesis, where an aqueous solution of NaBH_4 was injected into a solution of CuCl_2 , InCl_3 , and disodium citrate hydrate in diethylene glycol (see Fig. 13 for the electron microscopy image of as-prepared nanoparticles). The role of disodium citrate was not only to control the nucleation and stability of the $\text{Cu}_{11}\text{In}_9$ nanoparticles, but also to effectively suppress the particle-to-particle agglomeration. Recently, organic free Cu–In alloy nanoparticle precursor ink was prepared by NaBH_4 -assisted chemical reduction and used to fabricate a CuInSe_2 absorber layer, but only solar cells with a low PCE of 3.92% were reported.⁸⁷

Another interesting approach was reported by Jeong *et al.*,¹¹⁹ who used a mixture of nanoparticles of CuInSe_2 , CuSe , Cu_{2-x}Se , and In_2O_3 to fabricate CuInSe_2 devices with efficiencies of up to 8.2%. The multiphase nanoparticles in this study were produced *via* a microwave-assisted solvothermal synthesis. In microwave processing, due to the tendency of particles to precipitate in a fast and nearly simultaneous manner, the synthesis of particles with small size and narrow size distribution is possible.⁹⁵

Another interesting concept was introduced by Min Lim *et al.*,¹²⁰ reporting the formation of quaternary $\text{CuInS}_3\text{Se}_{1-x}$ nanoparticles *via* chemical welding of binary CuSe and In_2Se_3 nanoparticles at room temperature. Contrary to most reports,

Fig. 13 Electron microscopy of citrate-capped $\text{Cu}_{11}\text{In}_9$ nanoparticles: (a) SEM overview image, and (b) detailed bright-field STEM image. Reprinted with permission from ref. 86, Copyright 2011 American Chemical Society.

the coalescence and sintering of particles were performed in the liquid phase, and imposed by oppositely charging the CuS and In_2S_3 nanoparticles (schematically outlined in Fig. 14). To establish opposite charges on the particle surface, the nanoparticles were synthesized in the presence of polyacrylic acid (PAA) and polydiallyldimethylammoniumchloride (PDAA), respectively, for CuS and In_2S_3 nanoparticles.

Most of the studies discussed so far employed relatively crystalline nanoparticles. Nevertheless, due to the high melting temperature of crystalline particles, they might not be necessarily the best choice for device fabrication. Ahn *et al.*^{121,122} reported the synthesis and utilization of amorphous Cu–In–Se nanoparticles, aiming to benefit from the lower melting temperatures of such particles to assist an effective sintering during a post-thermal treatment. CuInSe_2 films formed from amorphous Cu–In–Se nanoparticles showed dense morphologies for particles modified by chelate complexation with ethanolamine. Recently, they demonstrated devices with efficiencies of up to 7.9% from modified amorphous nanoparticles.¹²³

3.3. Deposition from nanoparticles/precursor solution

Hybrid inks are interesting from the perspective of combining the advantages of particulate-based and molecular-based

Fig. 14 A schematic diagram representing the formation of $\text{CuInS}_x\text{Se}_{1-x}$ nanoparticles through electrostatically induced coalescence and sintering of binary CuSe and In_2Se_3 nanoparticles. Reprinted with permission from ref. 120, Copyright 2013, The Royal Society of Chemistry.

precursor solutions. In a hybrid ink of nanoparticles mixed into a precursor, the precursor solution can be used as a medium to provide effective binding between nanoparticles. Further, the particles can act as nucleation sites to promote grain growth and film densification. Cho *et al.*¹²⁴ developed a hybrid ink using a mixture of colloidal CuS nanoparticles and an indium precursor solution to form a dense layer of CuInSe_2 , demonstrating solar cells with efficiencies of over 6% after selenization. Similar device efficiencies were reported by Cai and coworkers based on spray deposition from a hybrid ink containing molecular precursors of CuCl_2 , InCl_3 , and thiourea mixed with CuS and In_2S_3 nanoparticles.¹²⁵ The inclusion of CuS and In_2S_3 nanoparticles in the precursor solution led to a substantial improvement in device performance, mainly as a result of increased J_{sc} and V_{oc} . The comparison between the J – V characteristics of devices made from a precursor solution and a nanoparticle/precursor solution is shown in Fig. 15.

3.4. Hybrid organic/inorganic solar cells

Inorganic semiconductor nanocrystals were investigated in combination with organic molecules or nanostructure metal oxides to combine attractive features of both classes of materials for applications like photodetectors and photovoltaics.^{126–128} Because of the high carrier mobility and tunable absorption properties, inorganic NCs are attractive to be used as electron accepting or donating materials for organic solar cells. These attractive features can be beneficial when combined with the low temperature processing of organic solar cells.¹²⁹

CuInS_2 and CuInSe_2 nanoparticles were used as electron acceptors^{130,131} or electron donors¹³² in combination with different polymers or organic small molecules to form a bulk-heterojunction solar cell structure. The semiconducting properties of CuInS_2 can be modified, depending on the ratio between Cu and In, to a p-type ($\text{Cu}/\text{In} > 1$) or an n-type ($\text{Cu}/\text{In} < 1$) semiconductor.¹³³

Fig. 15 J – V curve of the device fabricated from a nanoparticle incorporated precursor film (blue) and a precursor film without nanoparticles (red). Reprinted with permission from ref. 125, Copyright 2013 American Chemical Society.

In a blend of colloidal CuInS_2 nanoparticles with conjugated polymers, the process of charge transfer was observed by photoluminescence and photo-induced absorption spectroscopic measurements.^{134,135} However, due to the limitations imposed by the presence of organic ligands as well as surface traps on the nanoparticles, fairly low efficiencies were reported (PCEs < 1%).^{132,134–136} The intricacy of controlling the morphology is another decisive factor, influencing the performance of hybrid solar cells. Such issues could be largely overcome by an *in situ* formation of the inorganic nanocrystals directly inside an organic matrix. This approach has the advantages of eliminating the need for a separate nanoparticle synthesis and the use of an organic capping ligand.^{137,138} The *in situ* formation of CuInS_2 nanoparticles in an organic semiconductor was described by Rath *et al.*¹³⁹ and Maier *et al.*¹³¹ The process reported by Rath *et al.* is schematically described in Fig. 16, in which the CuInS_2 nanoparticles were directly formed in the matrix of the conjugated polymer, poly[(2,7-silafluorene)-alt-(4,7-di-2-thienyl-2,1,3-benzothiadiazole)] (PSiF-DBT), using easily thermally decomposable organometallic complexes, copper xanthates and indium xanthates. A mild annealing step at 200 °C was used to complete the fabrication of nanocomposite CuInS_2 /PSiF-DBT solar cells. A conversion efficiency of 2.8% was achieved, which is one of the highest efficiencies ever reported for polymer/CIS nanocomposite solar cells.

A summary of the solar cell results associated with the use of hybrid mixtures, *i.e.* nanoparticles/precursor and inorganic/organic, is given in Table 4.

Fig. 16 Schematic representation of the polymer/CIS nanocomposite formation. Reprinted with permission from ref. 139, Copyright 2011, Wiley VCH.

4. Solution processed kesterite solar cells

Kesterite-based compounds, *i.e.* $\text{Cu}_2\text{ZnSnS}_4$ (CZTS), $\text{Cu}_2\text{ZnSnSe}_4$ (CZTSe), and $\text{Cu}_2\text{ZnSn}(\text{S},\text{Se})_4$ (CZTSSe), are materials showing optical and electronic properties comparable to those of the chalcopyrite CuInS_2 , CuInSe_2 and $\text{Cu}(\text{In}, \text{Ga})(\text{Se}, \text{S})_2$ materials, however with the advantage of being composed of only abundant and economical elements.³¹ Among all, CZTS with an optimal bandgap of 1.5 eV and a large absorption coefficient of 10^4 cm^{-1} is one of the best absorber materials for solar cell mass production.¹⁴⁰ Despite the promising potential, there is still a significant performance gap between the best kesterite-based and chalcopyrite solar cells (see Fig. 1). The reason can be found in manifold complexities related to the crystal structure, stoichiometry, point defects and morphology of kesterite. Due to the narrower existence region of the kesterite phase compared to the analogous chalcopyrites, secondary phases and point defects are a serious challenge in this material system.^{23,141} Fig. 17 compares the calculated stable chemical potential range for chalcopyrite CuInSe_2 and kesterite $\text{Cu}_2\text{ZnSnS}_4$, showing the more complicated limit to the chemical potential region for the latter compound.

In order to close the performance gap with CIGSSe, further applied and theoretical studies are necessary to understand the underlying interfaces and corresponding defects of the CZTSSe system. Interestingly, the presently highest efficiency CZTSSe devices are based on fabrication *via* solution-processing methods. One of the major issues is the more volatile mix of elements (*e.g.* Sn) in the CZTSSe system, causing a severe limitation for the vacuum based techniques requiring post-thermal treatment at temperatures >400 °C.^{142,143} Although this problem is largely resolved by heat treatments under different chalcogen-containing (*e.g.* Sn) atmospheres,¹⁴⁴ the device efficiencies are still below those prepared by liquid-based processing.

4.1. Hydrazine solution processing of CZTS(e)

Currently, there are two types of hydrazine based solution processing routes: one is based on a hybrid mixture of nanoparticles and a precursor solution, which involves undissolved

Table 4 Survey of chalcopyrite solar cells fabricated based on deposition from the nanoparticles/precursor solutions and summary of hybrid chalcopyrite nanoparticles/polymer solar cells^a

Year	Absorber	J_{sc} (mA cm^{-2})	V_{oc} (mV)	FF (%)	PCE (%)	Deposition and solvent	Post-treatment	Description	Ref.

Zn particles and truly dissolved precursor solutions,¹⁴⁵ and another is a purely molecular based approach which involves all the chalcogenides fully dissolved at a molecular level.¹⁴⁶ Both of these approaches exhibited highly efficient solar cells. Originating from the previous works on hydrazine processed CIGSSe absorbers, Mitzi *et al.*¹⁴⁵ demonstrated the fabrication of CZTSSe thin film solar cells with 11.1% power conversion efficiency using a hydrazine-based hybrid approach. Quite recently, by optimizing the thickness of the CdS and transparent-conducting layers, Mitzi *et al.* improved the device efficiency to 12.0%.¹⁴⁷ Until today, this performance holds the highest reported efficiency for this material system. Another hydrazine-based approach was reported recently by Yang *et al.*¹⁴⁶ In this study, the hydrazine derivatives were designed to allow the effective incorporation of zinc compounds into hydrazine solution, forming a CZTS precursor solution that is homogeneous at the molecular level. Based on a deposition from this precursor solution and a subsequent selenization process, a solar cell with an efficiency of 8.08% was produced.

4.2. Non-hydrazine solution processing of CZTS(e)

Although among all available fabrication routes including both vacuum and non-vacuum based techniques, the hydrazine based approach has yielded the highest efficiency kesterite solar cells, as previously mentioned, the explosivity and toxicity of hydrazine extremely limit its application in large scale production.¹⁴⁸ It is hence essential to develop a relatively simple precursor route using less toxic solvents with comparable performance to those made from hydrazine based approaches.

4.2.1. Nanoparticle based precursors. During the past five years, there has been a rapid development in the field of nanoparticle based approach for fabrication of kesterite-based solar cells.^{149–153} Among all the hydrazine-free approaches to fabricate CZTSSe devices, the highest efficiency kesterite solar cells were reported based on using a nanoparticulate-based solution with a maximum PCE of 10.2%;¹⁵⁴ this is rather a close value to the 12% record CZTSSe solar cell fabricated by a hydrazine-based precursor solution. Since the first reported work in 2009 employing CZTS nanoparticles, produced by a hot

injection method, to fabricate thin film kesterite solar cells,¹⁵³ research in this field did draw a tremendous amount of attention. The efficiency was steadily increased from PCEs < 1% to 10.2% until 2012.^{145,149,154} In 2009, Guo *et al.*¹⁵³ reported a CZTSSe solar cell with an efficiency of 0.8% using pre-synthesized CZTS nanocrystals deposited on Mo substrates and a subsequent high temperature annealing in a Se atmosphere. At the same year and by optimizing the Cu/(Zn + Sn) and Zn/Sn ratios, the same group improved the solar cell efficiency to 7.2%.¹⁴⁹ The performance of solar cells was shown to be strongly dependent on the specific CZTS composition (Cu-poor and Zn-rich films usually tend to show higher device efficiency). The precise control of the final film composition, however, appeared to be difficult when quaternary CZTS nanoparticles were used as the starting precursor. Recently, Cao *et al.*¹⁵¹ reported another fabrication route based on the use of binary ZnS and ternary Cu_2SnS_3 (CTS) nanoparticles, allowing facile control of the final film composition with promising solar cell efficiencies of 8.5% (Fig. 18). Similar high device efficiencies were achieved by alloying CZTS with Ge nanoparticles;¹⁵⁵ by carefully controlling the relative cation ratios, this effective band-gap engineering resulted in CZTGeSSe solar cells with a slightly higher V_{oc} of 464 mV.

Similar to the particulate-based methods used for fabrication of CIGS devices, a mixture of metallic and metallic chalcogenide nanoparticles was used to form kesterite CZTS films. Based on a precursor solution containing a powder mixture of Cu_2S , Zn, Sn, and S nanoparticles dispersed in ethanol, Woo *et al.*¹⁵⁶ reported the fabrication of CZTS solar cells with the highest PCE of 5.14%.

Despite all these promising reports, there are still some unsolved problems concerning the use of nanoparticles. One major issue is related to the carbon residues remaining in the final film after high temperature selenization or sulfurization, promoting formation of a small-grained inter-layer in the film. Another problem is the trade-off between impurities left after the decomposition of the ligands and the need for high-quality dispersion precursors. To address the above issues, Carrete *et al.*¹⁵⁷ developed a multistrategy ligand exchange approach in the solution phase to remove the organic ligands. In this work,

Fig. 18 TEM pictures of (a) CTS and (b) ZnS nanoparticles and the corresponding (c) J - V curves of CZTSSe devices. Reprinted with permission from ref. 151, Copyright 2012 American Chemical Society.

they introduced an antimony salt to displace the organic ligands from the surface of CZTS nanoparticles (see Fig. 19, a schematic picture describing the ligand-exchange). Moreover, antimony effectively reduced the material melting point that promoted the diffusion-controlled crystallization. With an automated pulsed spray deposition followed by selenization treatment, homogeneous and carbon-free CZTSSe thin films were fabricated.

The current knowledge of particle synthesis allows the preparation of CZTS and CZTSe nanoparticles with a fine crystal structure and favorable chemical composition in various organic solvents; this makes the direct deposition of such nanoparticles at low processing temperatures feasible without high temperature selenization or sulfurization. The ultimate goal of this approach is to develop nanoparticle inks to deposit inorganic thin films under ambient or mild processing conditions, ideally in a high-throughput printing process, like a roll-to-roll process on flexible substrates. Recently, there have been some reports focusing on low temperature processing of CZTS nanoparticles. Korgel group reported a device efficiency of 0.23% utilizing the Au/CZTS/CdS/ZnO/ITO device structure without any post-thermal annealing process.¹⁵² The cause of such low device efficiency is largely due to the existence of insulating organic ligands on the large surface areas of CZTS nanoparticles, inhibiting the effective charge transport between the particles. Exchanging the long chain of the capping agent oleylamine by the short ligand pyridine and employing a solar cell architecture of ITO/CZTS/PCBM/Ca/Al, Saha *et al.*¹⁵⁸ demonstrated CZTS solar cells with an improved PCE of 0.9%.

Further improvement in device efficiencies can be expected by implementing effective approaches to overcome the presence of insulating organic ligands and to passivate the various trap sites on the particle surface.

4.2.2. Molecular based precursors. In the non-hydrazine molecular based precursor approach, one major concern is that the transition from a mixed metallic oxide or salt precursors to a single-phase multinary sulfide/selenide material may lack sufficient reaction efficiency. However, if one can well control this transition, reasonably high-performance devices can be demonstrated. Recently, there are two groups who reported high efficiency solar cells using non-hydrazine solvents. PCEs of 6% and 7.4% were reported based on using a mixture of ethanol solution with butyldithiocarbamic acid¹⁵⁹ and DMSO,¹⁶⁰ respectively. The use of a binder-free DMSO solution was reported for the first time by Ki *et al.*,¹⁶¹ demonstrating solar cells with a PCE of 4.1%. With some small modifications of processing, Schnabel *et al.*¹⁶⁰ significantly improved the device efficiency from 4.1% to 7.5%. The main modifications were made on post-thermal treatment and the phase-transformation process. The drying temperature was lowered from 580 °C to 300 °C and the selenization profile was modified from 500 °C, 20 min to 540 °C, 6 min. Owing to a shorter selenization time used, the problem with Sn loss was to a large extent solved and a homogeneous chemical composition was ensured. The cross-section SEM image of the CZTSSe film showed that the highly crystalline phase only forms on the top and bottom of the film, where no large grains can be found in the middle of the absorber layer, thus forming a trilayer-like structure (see

Fig. 19 Schematized view of the procedure representing the ligand-exchange of the long-chain OLA ligand with an inorganic salt SbCl_3 . Reprinted with permission from ref. 157, Copyright 2013 American Chemical Society.

Fig. 20(b)). These observations point to the possibilities of improving the device performance even further by modifying the processing route and the phase transformation profile.

Wang *et al.*¹⁵⁹ employed a molecular precursor solution comprised of a mixture of binary metallic precursor oxides of Cu_2O , ZnO , and SnO dissolved in a mixture of ethanol solution with butyldithiocarbamic acid, a similar method to the one developed for fabrication of high quality CIGS_{Se} layers.^{73,74} By optimizing the composition of CZTSe, solar cells with a device efficiency of 6.03% have been achieved. The advantage of this approach is the use of volatile less toxic ethanol as the main solvent and the formation of the CZTS phase at relatively low temperatures of 320 °C without any formation of binary and ternary chalcogenide phases.

4.2.3. Hybrid particles/precursor. Recently, Zong *et al.*¹⁶² reported an interesting hydrazine-free fabrication route similar to the hydrazine-based hybrid approach proposed by Mitzi *et al.*¹⁴⁵ but using a significantly less toxic solvent propylmercaptan (PM). The ink comprises of a Zn-PM precursor based solution mixed with the pre-formed readily dispersible ternary Cu_2SnS_3 (CTS) nanoparticles. Fig. 21(a) represents the schematic picture describing the formation of CTS nanoparticles, prepared by parallel dissolution of copper chloride, tin chloride and elemental S. Taking advantage of pre-formed CTS particles, the reaction pathway was effectively shortened, and the formation of undesired secondary phases was also avoided. After the film deposition, the absorber film was selenized at 450–550 °C for 60 min to complete the phase transformation to the targeted CZTSSe phase. Solar cells based on this absorber layer exhibited a V_{oc} of 440 mV, J_{sc} of 32.1 mA

cm^{-2} and FF of 51.9%, resulting in a solar cell with a PCE of 7.4%. Due to the simplicity and flexibility in this fabrication approach, *i.e.* the use of more environmentally benign solvent, avoiding a complex synthesis route for preparing the ternary CTS nanoparticles, and flexibility in controlling the composition and stoichiometry, this method has the potential to match the requirements for a scalable production through printing and roll-to-roll fabrication methods.

5. Summary and outlook

Depending on the method of preparation, Fig. 22 compares the absolute efficiency of the most efficient solution processed chalcopyrite solar cells published within the last five years, indicating a clear trend to better device efficiencies. The record published PCE of 15.2% based on the pure solution deposition,⁴⁹ and the certified 17.1% printed CIGSe solar cell on flexible foil announced by Nanosolar,¹⁶³ show the promising path of this technology, bridging the performance gap with the highest efficiency vacuum-based devices with a PCE of 20.4%.⁵ A similar progress can be also realized in the field of solution processed kesterite solar cells with reported maximum efficiencies of 10.2% for hydrazine-free processes and 12% for the hydrazine-based approach. Although the most efficient solution processed solar cells still belong to the category of hydrazine-based devices, with plenty of studies recently concentrating on non-hydrazine based devices, there has been also a rapid progress towards efficient hydrazine-free solar cells. As shown in Fig. 22, this progress can be clearly seen for both particulate and precursor-based devices. By summarizing the results in Tables 2–5, one can see that most of the studies employ high temperature selenization or sulfurization, where only sporadic studies reported solar cells without a high temperature crystallization process. The complex post-treatments and high temperature processing routes are the important cost-driving factors for the production of solar cell technology. The high temperature routes impose not only high energy costs, but also prohibit the use of cheap substrates needed for the low-cost solar cell fabrication. With further emphasis on the low temperature processing routes, the green formulations and ongoing focus on kesterite solar cells as an excellent replacement containing only

earth-abundant elements, printable multicomponent inorganic inks can lead to inexpensive fabrication for light absorbing thin films. To make this possible, significant amount of investigation seems to be still necessary to unravel the complexity in the synthesis chemistry, dissolution mechanisms, drying kinetics and phase formation of thin films and their relationship to various loss mechanisms in photovoltaic devices. The pace of development can be accelerated with the emergence of new concepts and an increasing attention on hybrid structures.
