Selective ion-permeable membranes by insertion of biopores into polymersomes†

Mihai Lomora,‡ Fabian Iteľ,‡ Ionel Adrian Dinu and Cornelia G. Palivan*

In nature there are various specific reactions for which highly selective detection or support is required to preserve their bio-specificity or/and functionality. In this respect, mimics of cell membranes and bio-compartments are essential for developing tailored applications in therapeutic diagnostics. Being inspired by nature, we present here biomimetic nanocompartments with ion-selective membrane permeability engineered by insertion of ionomycin into polymersomes with sizes less than 250 nm. As a marker to assess the proper insertion and functionality of ionomycin inside the synthetic membrane, we used a Ca^{2+} -sensitive dye encapsulated inside the polymersome cavity prior to inserting the biopore. The calcium sensitive dye, ionomycin, and Ca^{2+} did not influence the architecture and the size of polymersomes. Successful ionomycin functionality inside the synthetic membrane with a thickness of 10.7 nm was established by a combination of fluorescence spectroscopy and stopped-flow spectroscopy. Polymersomes equipped with ion selective membranes are ideal candidates for the development of medical applications, such as cellular ion nanosensors or nanoreactors in which ion exchange is required to support *in situ* reactions.

Introduction

In nature, both cells, and inner organelles as biocompartments preserve their functions and communicate by signaling with their environment *via* a permeable lipid membrane in which membrane proteins mediate the transport of molecules, which are vital for cell metabolism. Compartmentalization represents an extremely efficient organization of membranes and biomolecules that is needed to cope with a complex scenario of metabolic reactions in a confined space, and whose stability and functions are vital for life.¹ Taking inspiration from natural biocompartments, significant efforts have been made to produce compartments that mimic cells and organelles, either in terms of their membrane properties or of the reactivity of encapsulated biomolecules.^{2–4} Whereas lipid based compartments (liposomes) are straightforward systems for mimicking a cell/organelle membrane, and encapsulating biomolecules to perform specific reactions,⁵ their mechanical instability and the presence of membrane defects limit applications that require robust compartments.⁶ One elegant way to avoid these drawbacks, and at the same time to add new membrane properties, such as stimuli-responsiveness or external functionalization for targeting approaches, is to use

compartments generated from amphiphilic block copolymers. A particularly interesting way to generate polymer compartments with sizes in the nanometer range is to self-assemble amphiphilic copolymers with appropriate chemical and physical properties.⁷ Indeed, polymer vesicles (polymersomes) are spherical 3-D compartments surrounded by a synthetic membrane with greater stability than liposomes.⁸

The architecture of polymersomes offers three different regions for combination with biomolecules: the inner cavity for encapsulating hydrophilic molecules, the membrane for insertion of hydrophobic molecules, and the external surface for attachment of molecules, by chemical modification of the hydrophilic polymer block.^{9,10} From a topologic point of view, polymersomes are mimics of cellular compartments, which by combination with active compounds can also be designed to act and communicate similarly to intracellular organization. As a result of simultaneously possessing hydrophilic and hydrophobic molecules in a single compartment, various applications can be developed based on polymersomes. These range from drug carriers,^{11–13} and containers for contrast agents,¹⁴ up to nanoreactors,^{15–18} and artificial organelles.¹⁹ In addition, in a biomimetic approach, multicompartmentalized polymersomes have been introduced to allow reactions between different inner compartments encapsulated in a giant compartment.^{20–22} A key factor for controlling *in situ* reactions (either in a single compartment or in multi-compartments) is the permeability of the polymersome membrane,²³ which has to allow transport of molecules required for the reaction (substrates of enzymes, products). This can be achieved

in various ways by: (i) using a block copolymer, which forms a porous membrane,²⁴ (ii) chemical modification of the membrane to create pores,^{25,26} (iii) blending block copolymers with lipids followed by their extraction,²⁷ (iv) insertion of biopores,²⁸ and (v) reconstitution of channel porins.^{15,29–31}

The permeabilization of synthetic membranes by intrinsic or induced pores supports penetration of molecules with sizes smaller than the dimension of the pores, but they are non-selective in terms of specific molecules that are allowed to pass through. A strategy to introduce selective transport of ions/molecules through membranes is to insert biopores with specific functionality, as for example ionophores. A first example of a permeabilized membrane of giant polymer vesicles (GUVs) for calcium ions was obtained by insertion of selective and non-selective ionophores, including Lasalocid A, Alamethicin (U22324), and *N,N*-dicyclohexyl-*N',N'*-dioctadecyl-3-oxapentane-1,5-diamide (ETH5234).³² GUV membranes were permeabilized towards calcium ions by insertion of calcimycin A23187 as well, and served for development of a microreactor.³³ While interesting as a microreactor model, the system is not appropriate for medical applications, due both to the size and instability of GUVs, and the use of calcimycin A23187, with a medium efficiency in ion transport.³⁴

Introduction of selectivity of polymersome membranes should support specific reactions inside the cavities, or the development of nano-biosensors for molecules selected by their specific permeability. In particular, biosensors are in focus as diagnostic systems, because they can sense changes in biological responses, which are then converted to detectable and measurable signals.^{35,36} Such sensors based on nanoreactors have been developed recently, but only a few examples have been reported, either in solution³⁷ or immobilized on surfaces.³⁸ However, these sensors are based on the specificity of active compounds encapsulated inside nanoreactors, and are not mediated by a selective membrane, as is the case in natural biocompartments.

Here, we introduce polymersomes with sizes in the nanometer range, and membranes engineered to be selectively permeable to divalent ions in order to support applications that require transport of a desired ion through the membrane, such as for specific *in situ* reactions or nano-sensors. We selected poly(2-methyloxazoline)-*block*-poly(dimethylsiloxane)-*block*-poly(2-methyloxazoline) (PMOXA_x-PDMS_y-PMOXA_x) for vesicle formation, because this type of amphiphilic triblock copolymer self-assembles in polymersomes when appropriate molecular properties (block length, hydrophilic to hydrophobic ratio), and preparation conditions (method of preparation, buffer) are used.¹⁵ The membranes of such polymersomes are both stable and impermeable to ions and small molecules,³⁹ except oxygen species.⁴⁰ Various channel porins can be inserted into this type of membrane; for example outer membrane protein F (OmpF), which induces non-selective permeability for molecules ≤ 600 Da.¹⁵

As a model biopore, able to induce selective membrane permeability, we selected ionomycin, a carboxylic acid ionophore (divalent anion polyether, *M*_w 787.08 Da), produced by *Streptomyces conglobatus*. Ionomycin allows specific transport of divalent ions, such as Ca²⁺,^{41–43} which we selected because it

Fig. 1 Design of Ca²⁺-selective permeable membranes by insertion of ionomycin into polymersomes.

plays a pivotal role in biological systems where many cellular responses are regulated by an ON and OFF mechanism that is strongly correlated to the intracellular Ca²⁺ concentration.⁴⁴ In nature, calcium signaling is initiated by cells using both intra- and extracellular sources of Ca²⁺, which are controlled by channels, pumps and exchangers to provide cellular calcium homeostasis for the cell integrity. Any perturbation in the calcium regulating gates results in channelopathies correlated with severe diseases, such as muscle or neurological disorders.^{45,46} The advantages of ionomycin compared to other ionophores, as for example calcimycin, are a more efficient Ca²⁺ transport,³⁴ and its lack of fluorescence, allowing a non-interfering use with fluorescent molecules.^{34,47} A combination of light scattering (LS) and transmission electron microscopy (TEM) has been used to characterize the formation of biopore-equipped polymersomes and their stability. Both fluorescence and stopped-flow spectroscopy were used to evaluate in details whether there was functional insertion of the biopore, and thus selective permeabilization of the membrane. In a systematic manner we took into account the factors affecting the system, as for example the presence of solvent, the gradient of ionomycin or the gradient of Ca²⁺ concentration in order to obtain the optimum conditions for selective membrane permeabilization without affecting the architecture of polymersomes.

Our ion-selective permeable polymersome (Fig. 1) represents progress in the development of mimics of a cell membrane, and supports fine modulation of reactions inside the cavity or the functionality of biosensors based on ion specificity. The system represents an optimized candidate towards medical applications (in terms of vesicles size, efficacy of ionophore and the improved stability of the polymer membrane).

Experimental

Materials and methods

Asante Calcium Green (ACG) K⁺ salt, was purchased from TEFLabs Inc, ionomycin from Alomone Labs, and *N*-(2-hydroxyethyl)-piperazine-*N'*-(2-ethanesulfonic acid) sodium salt (HEPES), sodium chloride (NaCl), calcium chloride dihydrate (CaCl₂·2H₂O), and

ethanol (EtOH) from Sigma. All reagents and materials were used as received.

Preparation of polymersomes and insertion of ionomycin

Polymersomes were prepared by the film rehydration method⁴⁸ at room temperature using a PMOXA₆-PDMS₄₄-PMOXA₆ triblock copolymer.⁴⁹ Briefly, for each sample, 5 mg of the block copolymer was dissolved in 1 mL of ethanol and subsequently evaporated under reduced pressure (150 mbar) to render a thin film. This film was then rehydrated with: (i) 1 mL HEPES buffer (20 mM HEPES, 50 mM NaCl, pH = 7.4) (empty polymersomes), or (ii) 1 mL of 20 μ M ACG solution in HEPES buffer (polymersomes with entrapped ACG). The polymer suspensions were stirred overnight at room temperature (RT) and afterwards extruded (13 times) through a 200 nm pore-size polycarbonate (PC) membrane (Merck, Germany), using an Avanti mini-extruder (Avanti Polar Lipids, USA). Extravesicular dye was separated from polymersomes that contained entrapped dye by passage through a 20 cm³ in-house prepacked size exclusion column (Sephacrose 2B, Sigma Aldrich). Ionomycin was added to the polymersomes mixture from a stock solution of ionomycin in EtOH (1.17 mM). Ionomycin molecular dimensions were determined using Visual Molecular Dynamics (VMD) software.⁵⁰

Efficiency of the ACG entrapment process and ionomycin insertion in polymersomes

The concentration of encapsulated ACG in polymersomes was determined by UV-Vis spectroscopy at $\lambda = 517$ nm. For this, a value of 24 310 M⁻¹ cm⁻¹ for the extinction coefficient of ACG in HEPES buffer was obtained based on a calibration curve for the dye. The entrapment efficiency of the process (EEP) was determined as a percentage of the ratio between the concentration of ACG in polymersomes after encapsulation and purification (c_{ep}) and the initial concentration of ACG used for the film rehydration (c_i):⁴⁸

$$\text{EEP}[\%] = \frac{c_{ep}}{c_i} \cdot 100 \quad (1)$$

A calibration curve was obtained by measuring ionomycin absorbance at 280 nm, in the presence of polymersomes (an extinction coefficient of 5410 M⁻¹ cm⁻¹ was determined for ionomycin). The percentage of ionomycin inserted into the polymersome membrane was calculated after removal of the free ionomycin from the polymersome samples containing different amounts of ionophore, by size exclusion chromatography.

Preparation of giant unilamellar vesicles (GUVs)

For the generation of giant unilamellar polymeric vesicles (GUVs), 30 μ L of the polymer dissolved in EtOH (4 mg mL⁻¹) was spread on an ITO-coated glass plate. The polymer solution was dried in high vacuum for 2 h in order to form a smooth polymer film on the glass surface. A chamber was formed with an O-ring and filled with 100 mM sucrose solution containing 20 μ M of ACG. The chamber was closed with a second ITO-coated glass plate facing the ITO side to the solution, and then exposed to an AC current (2.5 V, 3.0 Hz) overnight at 20 $^{\circ}$ C.

Characterization techniques

Light scattering (LS). Dynamic and static light scattering (DLS and SLS) studies were performed on an ALV/CGS-8F goniometer (Langen/Hessen, Germany) equipped with a He-Ne laser power supply (JDS Uniphase, $\lambda = 632.8$ nm). Polymersome suspensions were serially diluted to polymer concentrations ranging from 0.0920 mg mL⁻¹ to 0.0125 mg mL⁻¹, and measured in 10 mm cylindrical quartz cells at 20 $^{\circ}$ C. Prior to light scattering measurements, all samples were filtered through 0.45 μ m hydrophilic, PTFE syringe filters (Millipore Millex-LCR) to remove any dust particles. The photon intensity auto-correlation function, $g^2(t)$, was determined by using an ALV/LSE-5004 digital correlator (at scattering angles between 30 $^{\circ}$ and 150 $^{\circ}$, with an angular step of 10 $^{\circ}$). A non-linear decay-time analysis supported by regularized inverse Laplace transform of $g^2(t)$ (CONTIN algorithm) was used to analyze the DLS data and to evaluate the apparent hydrodynamic radius (R_h) of polymersomes. The angle-dependent apparent diffusion coefficient was extrapolated to zero momentum transfer (q^2) using the ALV/static and dynamic FIT and PLOT 4.31 software. Angle and concentration-dependent SLS data were analyzed using Guinier plots and used to determine the apparent molecular weight ($M_{w,agg}$), the radius of gyration (R_g), and the second virial coefficient (A_2) of the polymersomes. The average aggregation number (N_{agg}) of self-assembled structures (Table S1, ESI[†]) was calculated from their $M_{w,agg}$ according with the eqn (2):

$$N_{agg} = \frac{M_{w,agg}}{M_w} \quad (2)$$

where M_w is the average molecular weight of the PMOXA₆-PDMS₄₄-PMOXA₆ triblock copolymer.⁴⁹

Transmission electron microscopy (TEM). TEM micrographs were acquired using a transmission electron microscope (Philips Morgagni 268D). 5 μ L of polymersome solutions were adsorbed for 1 min on glow-discharged carbon-coated copper grids. Then the samples were blotted, the grids were washed with pure water and negatively stained with 2% uranyl acetate solution.

UV-Vis spectroscopy. UV-Vis spectra were acquired on a SpectraMaxPlus 384 (Molecular Devices, Sunnyvale, USA) using a 96-well absorbance microplate.

Fluorescence spectroscopy. Diluted polymersome solutions containing entrapped ACG without, and with ionomycin, and in the presence of CaCl₂, were mixed in 3 mL quartz cuvettes and placed in a LS 55 Fluorescence Spectrometer (Perkin Elmer) for fluorescence and kinetic measurements. The samples were excited at $\lambda = 517$ nm and emission was monitored at $\lambda = 540$ nm (7.5 nm slits).

Stopped-flow spectroscopy with fluorescence detection. Samples consisting of polymersome suspensions loaded with ACG, without or with ionomycin, were injected into a SX20 stopped-flow apparatus (Applied Photophysics, UK), using a monochromator set at 517 nm and a cut-off filter of 530 nm. The kinetic data were fitted using a double exponential equation:

$$A(t) = \Delta A_1 \cdot \exp(k_1 \cdot t) + \Delta A_2 \cdot \exp(k_2 \cdot t) + A_{\infty} \quad (3)$$

where k_1 and k_2 are the observed rate constants for the first and second components of the double-exponential reaction,

respectively, and ΔA_1 and ΔA_2 , are the corresponding amplitudes for the first and second components of the double-exponential reaction. A_∞ represents the final value of the fluorescence intensity.

Surface (ζ) potential measurements. The ζ -potential of: (i) free calcium sensitive dye (ACG), (ii) empty polymersome solutions without ionomycin, in the absence of calcium ions, (iii) polymersomes with entrapped ACG solutions without ionomycin, in the absence of calcium ions, (iv) polymersomes with entrapped ACG solutions with ionomycin, in the absence of calcium ions, and (v) polymersomes with entrapped ACG solutions with ionomycin, in the presence of calcium ions was investigated. We used disposable folded capillary cells placed in a Zetasizer Nano ZSP (Malvern Instruments), at 25 °C.

CLSM imaging of GUVs and FCS measurements. Confocal laser scanning microscopy (CLSM) and fluorescence correlation spectroscopy (FCS) measurements were performed on a Zeiss LSM 510-META/Confocor2 laser-scanning microscope equipped with an Argon/2 laser ($\lambda = 514$ nm) and a 40 \times water-immersion objective (Zeiss C/Apochromat 40X, NA 1.2). Excitation power of the laser was 15 mW and the excitation transmission was set to 10%. For imaging of GUVs, the laser beam was guided through a dichromatic beam splitter (HFT 514), a secondary dichroic beam splitter (NFT 515), and a low pass filter (LP 530). GUVs were immobilized on microscopy slides by diluting the GUVs (sucrose solution) in HEPES buffer; the GUVs sink to the bottom of the glass slide and adhere on the surface. Images were taken before and after bleaching for 3 s at 100% transmission.

For FCS measurements, the diameter of the pinhole was set to 74 μ m, and the diffusion time for ACG (25 nM) in Hepes buffer was fixed in the fitting procedure. Empty polymersomes were incubated overnight with 20 μ M ACG at RT, then 10 μ L of these solutions were placed on microscopy glass slides, and FCS measured at an excitation transmission of 10% over 20 \times 10 s. Autocorrelation functions were fitted with a two-component model including triplet state.⁵¹ From the two-component fitting model, the percentages of fast-diffusing (free ACG) and slow-diffusing fractions (ACG-containing polymersomes) were obtained.

Z-scan FCS. GUV membranes were stained with Bodipy 630/650 NHS ester (Thermo Fisher Scientific Inc; Waltham, MA, USA) by the addition of 5 μ L of a 25 nM Bodipy stock solution in buffer to the immobilized GUVs on the glass surface. Z-scans were recorded as previously described,⁴⁹ except that a He-Ne laser was used ($\lambda = 633$ nm, 1% transmission at 15 mW).

Results and discussion

The process of generation of polymersomes with selective permeable membranes (Polsp) by insertion of biopores has to preserve both the architecture of the polymer vesicles and the functionality of the biopores which, depending on their functionality, should span or cross the entire membrane. The membrane permeabilization upon insertion of ionophores results from a selective transport of ions, which is mediated by the ionophore through the membrane. In this respect, we

selected PMOXA₆–PDMS₄₄–PMOXA₆ copolymers with a membrane thickness of 10.7 nm (almost twice as thick as a lipid bilayer)⁴⁹ and ionomycin, a model ionophore for efficient membrane permeabilization for Ca²⁺ ions.

Architecture of polymersomes before and after ionomycin insertion

We combined light scattering (LS) and transmission electron microscopy (TEM) to evaluate the formation of polymersomes using specific conditions aimed at not affecting ionomycin functionality. We were interested in establishing whether the engineering of Polsp is influenced in terms of polymersomes size, shape and stability by the components of the system: *i.e.* whether the selected calcium sensitive dye (ACG), ionomycin used for polymer membranes permeabilization, or the presence of calcium ions, influences the self-assembly process.

First, 3-D supramolecular assemblies were formed in the presence of ACG. TEM indicated the formation of spherical structures upon encapsulation of ACG, with radii around 100 nm (Fig. 2A), and no changes were observed in either shape or size of the 3-D supramolecular assemblies upon addition of ionomycin (Fig. S1, ESI[†]), or ionomycin and CaCl₂ (Fig. 2B).

To obtain insight into the size, shape and stability of the 3-D supramolecular assemblies that resulted from encapsulation of ACG, in the presence of ionomycin, or/and Ca²⁺ ions, we also used light scattering measurements. Their hydrodynamic radius (R_h) was determined by dynamic light scattering, whilst the radius of gyration (R_g) was measured by static light scattering (Table 1).

The 3-D supramolecular assemblies resulting from encapsulation of ACG, and in the presence of ionomycin or/and Ca²⁺ ions, have radii of gyration around 100 nm, in agreement with the values obtained from TEM micrographs (Table 1 and Fig. 2). The observation of a monomodal distribution peak with a narrow

Fig. 2 TEM micrograph of A₆B₄₄A₆ polymersomes with encapsulated ACG (A), and in the presence of 3.74 μ M ionomycin and 830 μ M CaCl₂ (B).

Table 1 Size of 3-D assemblies of PMOXA₆–PDMS₄₄–PMOXA₆ without and with ionomycin, and in the presence of 830 μ M CaCl₂

Size and stability of calcium sensing nanodevices	DLS/SLS		
	R_g [nm]	R_h [nm]	$\rho = R_g/R_h$
A ₆ B ₄₄ A ₆	115	128	0.89
A ₆ B ₄₄ A ₆ + ionomycin	132	145	0.91
A ₆ B ₄₄ A ₆ + ionomycin + CaCl ₂	117	122	0.96

size distribution indicates that only one population of 3-D supramolecular structures is present in solution (Table S1, ESI†, PDI values). For the 3-D supramolecular assemblies, the structural parameter ρ ($\rho = R_g/R_h$) has values of 0.89–0.96, which are close to the value of 1.0 for hollow spheres. Therefore, the 3-D supramolecular assemblies are polymersomes after encapsulation of ACG, and there is no influence on their architecture when ionomycin is inserted into their membranes and/or Ca^{2+} ions are present in their surroundings. Moreover, within the investigated concentration range, there was no significant variation in their radii, indicating that the measurements were in a concentration regime without interactions between polymersomes. The increase in $M_{w,agg}$ and N_{agg} by addition of ionomycin confirms the presence of ion-carriers in the self-assembled structures, in agreement with reports indicating that R_h and N_{agg} values of nano-objects are highly dependent on the length and content of the constituent molecules^{52,53} (Table S1, ESI†). By changing the hydrophobic to hydrophilic ratio of the membrane, a nonlinear increase of N_{agg} has been observed, whilst the size of the vesicles only slightly increased,⁵³ which is also the case for our polymersomes upon insertion of ionomycin (Table 1 and Table S1, ESI†). In addition, the insertion of the charged molecules of ionomycin in the hydrophobic domain of the membrane decreased the ζ -potential of polymersomes, and contributed to the increase in the N_{agg} value (Tables S1 and S2, ESI†). The stability of supramolecular assemblies in the absence and in the presence of ionomycin, as well as upon addition of CaCl_2 , is supported by the very small and slightly negative values of the second virial coefficients ($A_2 \sim 10^{-8}$). Both the low PDI values and the very low values of the second virial coefficient A_2 indicate no interaction of polymersomes, which would result in a merge of vesicles. Therefore, the change in $M_{w,agg}$ and N_{agg} values is attributed only to the insertion of the ionophore into the vesicle membrane.

By dividing the fraction of encapsulated ACG by the initial amount used for encapsulation, we calculated the entrapment efficiency process of ACG as 7.5%.

Polymersomes with inserted and functional ionomycin

Although ionomycin was successfully inserted and functional in lipid membranes,⁵⁴ it is interesting to study whether it is still able to mediate Ca^{2+} transport when inserted in polymer membranes with double the thickness of lipid membranes. Ionomycin has a diameter of 1.5 nm, as calculated from the crystal structure of the calcium complex⁵⁵ (Fig. S2, ESI†).

First, we evaluated the changes in fluorescence intensity of the free ACG, induced by the presence of a CaCl_2 solution under similar conditions to those used for assessing ionomycin functionality in ACG-loaded polymersomes. The fluorescence intensity of ACG was evaluated in the presence of ionomycin, and EtOH was used for ionomycin solubilization. Neither ionomycin nor EtOH had any influence on ACG fluorescence intensity (Fig. S3, ESI†). Secondly, the change in fluorescence intensity of encapsulated dye was evaluated, both without and in the presence of ionomycin, to provide evidence of eventual defects in the polymer membrane (in the absence of ionomycin), and on successful insertion of ionomycin. If ionomycin is inserted

Fig. 3 Ca^{2+} influx through $\text{A}_6\text{B}_{44}\text{A}_6$ polymer membrane. ACG-loaded $\text{A}_6\text{B}_{44}\text{A}_6$ polymersomes (black curve), with EtOH (red curve), at the optimum concentration of $3.74 \mu\text{M}$ ionomycin (blue curve), in the presence of $830 \mu\text{M}$ CaCl_2 .

into the membrane, Ca^{2+} ions from the environment of the vesicles will penetrate the membrane, resulting in an increase in fluorescence intensity of the encapsulated dye.

ACG-loaded polymersomes without ionomycin had low fluorescence intensity in the presence of $830 \mu\text{M}$ CaCl_2 (Fig. 3, black curve), and did not change in the presence of EtOH (Fig. 3, red curve). The slight increase in fluorescence intensity upon addition of CaCl_2 may be due to a small fraction of ACG that was incompletely removed during purification of the ACG-containing polymersomes.

It was only when ionomycin was added that the fluorescence intensity increased significantly. This indicates a calcium influx through the ionomycin (Fig. 3, blue curve), and thus demonstrates their proper insertion and functionality. The fluorescence intensity of ACG-loaded polymersomes increased with increasing ionomycin concentration in a range of 117–3740 nM (in the presence of $830 \mu\text{M}$ CaCl_2), at which maximum of fluorescence intensity was reached (Fig. S4, ESI†). For low initial amounts of ionomycin, an insertion efficiency close to 100% was obtained, which slightly decreased upon increasing the ionomycin amount (for $3.74 \mu\text{M}$, the insertion efficiency was of 93%). To calculate the number of ionomycin molecules/polymerosome we used a simple model based on uniform distribution of ionomycin molecules in polymersomes, and neglected the statistical character of the self-assembly process of polymerosome formation. This results in approx. 9.14×10^3 ionomycin molecules/polymerosome for the initial amount of $3.74 \mu\text{M}$ ionomycin, and 2.28×10^{11} polymerosomes (obtained from light scattering data).

Further increases in ionomycin concentration up to $10.40 \mu\text{M}$ resulted in lower increases in the fluorescence intensity of the encapsulated ACG. It indicates that a high amount of ionomycin influence the transport of Ca^{2+} ions through the polymerosome membrane by unspecific attachment of ionomycin molecules on its external surface or by formation of 1:2 Ca-ionomycin

complexes (Fig. S4, ESI†). Only 80% of the initial ionomycin amount (10.4 μM) was inserted in polymersome membrane (Fig. S5, ESI†). At higher initial concentration of ionomycin (15 μM) a significant fraction of polymersomes did not preserve their architecture (Fig. S6B, ESI†), resulting in leakage of the entrapped dye, as observed by the very high fluorescence intensity (Fig. S4, ESI†).

To obtain insights into the efficiency of calcium influx through the ionomycin ion-carrier in the first short period of time (≤ 15 s), we used stopped-flow spectroscopy (Fig. S7, ESI†). An increase in the fluorescence intensity of the ACG in polymersomes upon insertion of 3.74 μM ionomycin was observed, in agreement with the behavior of Polsp, as established by fluorescence spectroscopy. Ca^{2+} ions are transported at a fast rate by the functional inserted ionomycin, resulting in a instant Ca^{2+} -selective and permeable polymer membrane.

The mechanism of membrane permeabilization for Ca^{2+} ions upon insertion of ionomycin was further investigated by evaluating diffusion within a very similar triblock copolymer membrane ($\text{A}_7\text{B}_{49}\text{A}_7$) of the fluorescent dye molecule Bodipy, which is similar in size to ionomycin (Fig. S8 and Table S3, ESI†). The analysis of the diffusion by Z-scan FCS shows that Bodipy has a free-diffusion character ($t_0 = 0$, Fig. S8B, ESI†) as already observed for fluid phase of lipid membranes.^{49,56} This indicates that PMOXA-PDMS-PMOXA triblock copolymer membranes provides a fluid homogenous hydrophobic medium, in which the ionophores are able to freely move. We have recently showed for a library of polymer membranes that the fluidity of such polymersome membranes based on PMOXA-PDMS amphiphilic block copolymers is similar to the fluidity of lipid bilayers.⁴⁹

Studies of ionomycin in model liposome membranes revealed a Ca^{2+} permeabilisation of the membrane by formation of Ca-ionomycin complexes, and transport through the membrane.^{41,54} Interestingly, calcium transport through polymersome membranes, which are twice thicker than lipid membranes (10.7 nm thickness), was successful upon insertion of ionomycin, resulting from the appropriate fluid environment of the membrane.⁴⁹

Sensitivity of the calcium selective membrane of polymersomes: nano-sensor functionality

Intracellular calcium concentrations vary from 100 nM, considered as the concentration when cells are at rest, up to 1 μM when processes inside cells are activated. In the extracellular space, the calcium amount can be as much as 10^4 -fold higher than the intracellular concentrations.⁵⁷ As in a biomimetic approach, since our Ca^{2+} selective polymersomes were intended to sense calcium amounts in various biological conditions, we were interested in determining the lowest concentration of Ca^{2+} that can be sensed by our polymersomes containing ionomycin. In order to do this, we varied the concentration of Ca^{2+} in the environment of Polsp using the optimum concentration of 3.74 μM ionomycin (Fig. 4). Polsp respond to the presence of 100 μM CaCl_2 , resulting in an increase of the fluorescence intensity of encapsulated ACG. Increased concentrations of CaCl_2 induced a higher fluorescence intensity of Polsp, up to 830 μM CaCl_2 . Significant increases in the initial concentration

Fig. 4 Optimum concentration of CaCl_2 . ACG-loaded $\text{A}_6\text{B}_{44}\text{A}_6$ polymersomes without ionomycin, in the presence of EtOH and 830 μM CaCl_2 (red bar), compared with ACG-loaded $\text{A}_6\text{B}_{44}\text{A}_6$ polymersomes equipped with 3.74 μM ionomycin and increasing concentrations of CaCl_2 (blue bars). Error bars are shown as standard deviations of three individual measurements.

of CaCl_2 in the environment of polymersomes resulted in a plateau and slight decrease of the fluorescence intensity from encapsulated ACG (a saturation effect). Similar behavior has been reported for the initial rate of calcium transport through liposome membranes as function of Ca^{2+} concentration.⁵⁴ The saturation effect for high Ca^{2+} concentrations was explained by a favored formation of 1 : 2 Ca-ionomycin complexes, which decrease the efficiency of Ca transport through the membrane.^{41,54}

Interaction of ACG with the polymer membrane

We used fluorescence correlation spectroscopy (FCS)^{19,58} to investigate why a slight increase in ACG fluorescence intensity appears in ACG-containing polymersomes without ionomycin after purification by size exclusion chromatography (Fig. S9, ESI†). FCS provides information on the sizes of particles by determining their diffusion time through the confocal volume of the laser beam. The short diffusion time of free-diffusing ACG in HEPES buffer ($\tau_{\text{d,ACG}} = 40$ μs) is typical for small molecular mass fluorescent dyes. Interaction of ACG with the polymersome membrane was assessed by adding ACG (20 μM) to empty polymersomes, which initially showed no fluorescence signal. After overnight incubation, the autocorrelation function of the fluorescence signal could be fitted with a bimodal model, which indicates the presence of two different populations of diffusing particles in the solution: a fraction of free ACG, and a second population with a significantly slower diffusion time ($\tau_{\text{d,vesicle}} \approx 7000$ μs). As the second population has a diffusion time characteristic of polymersomes with hydrodynamic radii of 50–100 nm,⁵⁸ this fraction represents polymersomes to which ACG is attached by nonspecific binding. To gain more details about this nonspecific interaction of ACG with the polymersomes membrane, we formed giant unilamellar vesicles (GUVs) with entrapped ACG, and visualized them by confocal laser scanning microscopy (CLSM). CLSM micrographs

(Fig. S10, left, ESI†) revealed GUVs containing free ACG molecules in the intravesicular volume. Upon increasing the laser intensity, the encapsulated dye was bleached, and the fluorescence intensity of the GUV membrane clearly indicates that the dye is interacting with the membrane (Fig. S10, right, ESI†). This behaviour was unexpected, due to the hydrophilic nature of ACG, and explains the slight increase of the fluorescence intensity of ACG-containing polymersomes upon addition of CaCl_2 (Fig. 3, black curve).

To take into account both fractions of ACG (encapsulated and attached to the membrane), we analysed the stopped-flow data by a double-exponential equation. The change over time in the intensity of the fluorescence signal upon mixing the ACG-containing polymersomes with CaCl_2 solution indicates that there are two kinetic processes taking place. The kinetic parameter of the first exponential term ($k_1 \approx 4 \text{ s}^{-1}$) obtained from a sudden increase in fluorescence intensity had similar values for ACG-containing polymersomes, ACG-containing polymersomes upon addition of EtOH, and Polsp (Table S3, ESI†). Therefore this parameter describes the interaction of Ca^{2+} ions with ACG molecules attached on the outer surface of the polymersome membrane. The kinetic time constant of the second exponential term (k_2) is ~ 50 times slower than for ACG-containing polymersomes without ionomycin ($k_2 \approx 0.8 \text{ s}^{-1}$) in the presence of CaCl_2 . When ACG-containing polymersomes contained ionomycin, k_2 was three times higher ($k_2 = 0.27 \text{ s}^{-1}$) in the presence of CaCl_2 , indicating that transport of Ca^{2+} ions through the membrane occurs as a result of functional insertion of ionomycin. In addition, both the amplitude of the second time rate (ΔA_2), related to the change in the signal intensity of the encapsulated dye, and the amplitude (ΔA_1), related to the dye attached to the membrane, are almost double for the Polsp compared to the ACG-containing polymersomes without ionomycin (Table S3, in ESI†). The higher value of ΔA_2 in the case of Polsp is related to the freely diffusing dye molecules inside the polymersome cavity, which react with Ca^{2+} ions that diffuse through the ionomycin. The difference in ΔA_1 values between Polsp and ACG-containing polymersomes, indicates that ACG is also attached to the inner surface of the membrane, as expected due to the symmetric character of membrane formation by the self-assembly process.

Overall, the stopped-flow parameters indicate a selective permeabilization of the membrane by appropriate and functional insertion of ionomycin, and give an insight into the interaction of the selected dye with the polymer membrane.

Conclusions

We have introduced synthetic compartments with sizes in the nanometer range (polymersomes) equipped with ionomycin in order to induce selective membrane permeability for supporting applications in which it is necessary to provide an influx of ions to the inner cavity for *in situ* reactions, or to sense low changes in the concentrations of ions in the environment. Polymersomes with ionomycin inserted in their membrane were produced by self-assembly in dilute aqueous solutions, as a straightforward mild method. $\text{PMOXA}_x\text{-PDMS}_y\text{-PMOXA}_x$

amphiphilic copolymers were used to generate polymersomes, with a membrane thickness of 10.7 nm, in order to see whether functional insertion of ionomycin (1.5 nm size) is possible in such thick membranes. Ionomycin was successfully inserted into membranes up to $3.74 \mu\text{M}$, without affecting the stability and architecture of the polymersomes, and allowed a rapid influx of Ca^{2+} ions through the synthetic membrane, as established by a combination of fluorescence spectroscopy and stopped-flow spectroscopy. Polymersomes equipped with ionomycin allowed a rapid sensing of Ca^{2+} ions in the concentration range $100\text{--}860 \mu\text{M}$, and the rate of Ca^{2+} transfer was evaluated for the first time in a synthetic membrane. This concentration range covers both intracellular and extracellular conditions, and thus supports possible biological applications as sensitive cellular ion sensors, or for the development of nanoreactors in which an influx of specific ions is necessary for reactions inside the inner cavity. By a systematic study of the factors affecting the insertion and functionality of the ionophore in polymersome membranes we were able to successfully obtain a selective nanosized polymersome membrane as an optimized candidate towards medical applications (in terms of vesicles size, efficacy of ionophore and the improved stability of the polymer membrane). In addition, our selective ion polymersomes can support applications in environmental science, food technology or catalysis, because they are able both to shield the encapsulated molecules from harsh external conditions, and to sense a large ionic range with rapid and selective efficacy.

Funding sources

We gratefully acknowledge the financial support provided by the Swiss National Science Foundation, the National Center of Competence in Research Nanoscale Science, and the National Center of Competence in Molecular Systems Engineering.

Acknowledgements

We thank Prof. W. Meier from the University of Basel for providing the amphiphilic block copolymers, G. Persy and Adrian Najer (University of Basel) for the TEM-measurements. ML thanks Dr Mariana Spulber, Ina Andrea Ontiveros Casas, and Serena Rigo (University of Basel) for preliminary experiments on ionomycin insertion and to Samuel Lörcher (University of Basel) for the synthesis of $\text{A}_7\text{B}_{49}\text{A}_7$ triblock copolymer. ML and FI acknowledge Dr Reinhard Kissner (Laboratory of Inorganic Chemistry, ETH Zurich) for providing support and useful discussions related to stopped-flow measurements. Dr B. A. Goodman is thanked for editing the manuscript.
