**Introduction**

Metal sensor proteins\(^1\)–\(^5\) display high selectivity for both essential and toxic metal ions, as demonstrated by representative members of the MerR family,\(^6,7\) such as the Cu\(^{1+}\)-sensing CueR, Zn\(^{2+}\)-sensing ZntR, and Hg\(^{2+}\)-sensing MerR.\(^8\) In this work we have attempted to design a peptide with a broader metal ion binding profile. In a biotechnological perspective, overexpression of such a peptide in suitable bacteria could endow the cells with the capacity to sequester metal ions, including toxic elements, from the environment.\(^9\) Additionally, elevated levels of such a peptide could ensure metal ion buffering of the cytosol, allowing the bacterium to survive in harsh conditions of both deprivation and over-exposure to metal ions in the surrounding medium, and serve as an engineered organism with improved properties for biomining and bioremediation.\(^10\)–\(^12\)

The template for the design was the Cu\(^{1+}\) binding loop of CueR from V. cholerae, SCPGDQGSDCP. In the related sequence from E. coli, Cu(i) ion is coordinated by two cysteines in a linear coordination geometry.\(^8\) The peptide is also expected to possess the capacity to bind the soft Hg\(^{2+}\) ion, due to the thio-lphilicity of this ion. In order to broaden the metal ion binding profile, and increase the peptide solubility, proline to histidine and proline to serine substitutions were introduced at positions 3 and 11, respectively. The positions of substitutions were chosen to increase ligand-flexibility, and to mimic the presence of His and Ser at these positions in some of the metalloregulatory MerR family members.\(^8\) The modifications were expected to promote the coordination of the borderline soft/hard Zn\(^{2+}\) ion. In a recent study we demonstrated that this designed 12-mer HS peptide (see Scheme 1) forms various species with Cd\(^{2+}\), including loop structures and metal ion bridged bis-ligand complexes, depending on pH and metal to ligand ratio.\(^13\)

Zn\(^{2+}\) is rather promiscuous in terms of coordination characteristics as compared to the clearly soft, often two-coordinated...
Hg\textsuperscript{II}. In general, Zn\textsuperscript{II} can easily adopt four-, five- or six-coordinate environments.\textsuperscript{14} Nevertheless, in zinc-containing enzymes and proteins the most typical coordination number is four.\textsuperscript{14,15} The preference of Zn\textsuperscript{II} for a tetrahedral coordination geometry in proteins is supported by detailed statistical analyses of crystal structures of zinc-containing proteins deposited in the Protein Data Bank (PDB).\textsuperscript{16,17} Five- and six-coordinated Zn\textsuperscript{II} centers are typically present due to the complementary coordination of solvent or inhibitor molecules in zinc-containing enzymes.\textsuperscript{17} Depending on the type of zinc-centers the abundance of Cys and His side chains significantly varies in the donor set patterns (number and type of bound donor groups). At catalytic zinc-centers any three N, O or S donors of Cys, His, Asp and Glu residues bind Zn\textsuperscript{II} in a 4–5 coordinate distorted-tetrahedral or trigonal-bipyramidal geometry, with His being the predominant ligand.\textsuperscript{18} A water molecule is always found in such centres. His and Asp donors are dominant at the co-catalytic zinc-sites consisting of two or three metal ions in close proximity, two of which are bridged by one of the amino acid side chains or a water molecule.\textsuperscript{18} Cysteines, however, are not utilized at these motifs. Four protein side chain ligands are bound to Zn\textsuperscript{II} in a tetrahedral or distorted tetrahedral geometry at structural zinc-sites.\textsuperscript{18} Such a binding mode is characteristic for e.g. the nucleic acid binding zinc finger proteins\textsuperscript{15} and for the zinc-clusters in metallothionines.\textsuperscript{19} In all classes of the structurally diverse zinc fingers\textsuperscript{20,21} Zn\textsuperscript{II} ions are ligated by a combination of four Cys/His side chain donors, at least two of which are Cys thiolates.\textsuperscript{15} Thiolate donors, complemented with side chain carboxylates and His-imidazoles, are also typical at the metalloregulatory Zn\textsuperscript{II} binding sites in various zinc sensor proteins, however, coordination number and geometry appears to be more decisive in metal ion selectivity than donor ligand types.\textsuperscript{15}

Hg\textsuperscript{II} can tolerate various coordination numbers and geometries, although, six-coordination is much less common than for the other two group 12 metal ions Cd\textsuperscript{II} and Zn\textsuperscript{II}.\textsuperscript{22} Linear two-coordinate, trigonal planar or T-shaped three-coordinate or tetrahedral four-coordinate structures are representative for complexes with monodentate ligands and higher coordination numbers might be accessible mostly with multidentate compounds.\textsuperscript{22,23} Hg\textsuperscript{II} forms complexes with coordination number 2 more commonly than any other metal ion,\textsuperscript{22} which can be explained by relativistic effects.\textsuperscript{24} Low coordination numbers are characteristic for complexes formed with thiolates, a class of ligands displaying an outstanding affinity towards the large and soft Hg\textsuperscript{II} ion,\textsuperscript{25} and in biological systems Hg\textsuperscript{II} is usually complexed by low molecular weight thiolates or by the Cys side chains of proteins.\textsuperscript{26} Amongst others, some representative examples are provided by the bacteriophage structure.\textsuperscript{27} The Hg\textsuperscript{II} : CNase interaction is important to note that the deprotonation of the cysteine residue at pH > 4.0–9.0 (Fig. 1). This suggests that the thiolate groups of \textit{HS} are bound to Hg\textsuperscript{II} from acidic to alkaline pH. It is important to note that the deprotonation of the cysteine residues of the free peptide between pH ~ 8–10 is accompanied by the appearance of an n → σ* transition around 230–240 nm characteristic for deprotonated thiols.\textsuperscript{36,37} (Fig. 1 and S2†), and as this is absent for the Hg\textsuperscript{II}–\textit{HS} species, we infer that the \{HgS\}_\text{3} coordination geometry is formed at pH lower than 4.

The pH-dependent absorbances detected for the sample containing 0.5 equivalent of Hg\textsuperscript{II} compared to \textit{HS} are in between the values observed for the ligand alone and the

**Results and discussion**

**UV absorption and SRCD studies monitoring the formation of thiolate–metal ion bonds and ligand structure**

Comparison of pH-dependent series of UV-spectra in the presence of 0, 0.5 and 1.0 equivalent of Hg\textsuperscript{II} or Zn\textsuperscript{II} as compared to the ligand provides information on the interaction of the metal ions with donor groups of \textit{HS}. The occurrence of S → Hg\textsuperscript{II} ligand to metal charge transfer (LMCT) transitions\textsuperscript{25,33} upon the addition Hg\textsuperscript{II} to the peptide imply that the cysteine side chain thiolate groups of the ligand are coordinated to Hg\textsuperscript{II} already at low pH (see the full spectra in ESI, Fig. S1A†).

The Hg\textsuperscript{II} : \textit{HS} 1 : 1 system shows almost a constant absorbance at λ = 230 nm at pH = 4–11 that is significantly higher than the absorption observed for the ligand in the absence of metal ion between pH ~ 4.0–9.0 (Fig. 1).
Hg\textsuperscript{II}-HS 1:1 system at any pH (Fig. 1). This suggests that ∼50% of the cysteine residues are bound to Hg\textsuperscript{II} even under acidic conditions and the remaining thiol groups deprotonate in parallel with the free ligand. The spectra recorded in the presence and absence of Hg\textsuperscript{II} reflect that the S\textsuperscript{−} → Hg\textsuperscript{II} charge transfer transitions are located below λ = 220 nm (ε\textsubscript{215} nm ∼ 15 900 M\textsuperscript{−1} cm\textsuperscript{−1}) independently of the pH and metal ion to ligand ratio (see the difference spectra of Hg\textsuperscript{II}-HS 1:1 and the free ligand in Fig. S3†). Such high energy LMCT transitions and the observed molar absorbances imply that two thiolates are coordinated to the metal ion, as proposed in previous reports on Hg\textsuperscript{II} – oligopeptide model systems. Three or four Hg\textsuperscript{II}-bound thiolates in a trigonal/tetrahedral coordination geometry would result in LMCT peaks or shoulders at lower energies\textsuperscript{44} which is not observed here even in the excess of HS over Hg\textsuperscript{II} indicating that metal ion bridged species are not formed.

In contrast to Hg\textsuperscript{II}, the LMCT band characteristic for S\textsuperscript{−}–Zn\textsuperscript{II} interactions in zinc(ii)-bound proteins\textsuperscript{32–34} and peptides\textsuperscript{45–49} emerges only above pH ∼ 5.0 in the solutions of Zn\textsuperscript{II} and HS (Fig. 2 and S4A–B†), reflecting the expected, substantially weaker affinity of Zn\textsuperscript{II} towards the ligand. A remarkable spectral change, i.e. a further absorbance increase occurs above pH ∼ 7.5 in the presence of one equivalent Zn\textsuperscript{II} per HS. A similar, but less pronounced spectral change, attributed to the formation of hydroxo mixed ligand species, was also observed in the Zn\textsuperscript{II}-complex of a related 12-mer peptide\textsuperscript{50} however, at a higher pH. Thus, the metal bound water appears to display a lower pK\textsubscript{w} of 8.65 in the Zn\textsuperscript{II}-HS complex, vide infra (potentiometric data).

The A\textsubscript{230 nm} vs. pH curve obtained for the Zn\textsuperscript{II}-HS 0.5:1 sample runs in between those of the free peptide and the equimolar system in the whole studied pH-range (Fig. 2). The observed profile is closer to that seen in the presence of 1 eq. Zn\textsuperscript{II} between pH 5–9, contrary to the data recorded for Hg\textsuperscript{II}. Thus, a more complex speciation must occur for Zn\textsuperscript{II}, with more than half of the thiolates bound to the metal ion at a stoichiometry of 0.5:1 Zn\textsuperscript{II}:HS, indicating the formation of metal bridged species. At high pH, however, the absorbances detected for twofold ligand excess seem to be ca. the averages of those of the free ligand and the equimolar sample (see Fig. 2, S2 and S4†), suggesting similar speciation at any metal ion to ligand ratios.

In order to gain information on the metal ion induced conformational change of the peptide SRCD (synchrotron radiation circular dichroism) spectra were recorded both for Hg\textsuperscript{II} and Zn\textsuperscript{II} complexes. Previously we have demonstrated that HS displays a disordered structure with varying levels of transient helicities\textsuperscript{,11} represented by an intense negative CD-extremum slightly below 200 nm and a less intensive shoulder around 220 nm.\textsuperscript{44,47,51,52} Addition of Hg\textsuperscript{II} to the acidic solution of HS results in a notable decrease of the negative peak at λ ∼ 198 nm while the shoulder is less affected (Fig. 3). A similar type of change was reported to accompany the Hg\textsuperscript{II}-coordi-
nation of a 18-mer peptide, comprising the metal binding loop of MerP possessing a CAAC motif. The spectral change was assigned to the folding of the peptide to a thermodynamically (but not necessarily kinetically) stable conformation, although the reduction of the negative ellipticity around 200 nm was also observed with other metal ions and two other peptide derivatives with alterations in the metal binding sequence (CCAA and CACA). By all accounts, Hg II-binding to HS clearly induces a conformational change of the ligand towards a loop structure, presumably similar to the metal-HS clearly induces a conformational change of the ligand towards a loop structure, presumably similar to the metal-HS clearly induces a conformational change of the ligand towards a loop structure, presumably similar to the metal-HS clearly induces a $^a$ log $\beta$ values for the protonation processes of HS, re-determined in the present study are: $\log \beta_{101} = 31.68$, $\log \beta_{102} = 28.33$, $\log \beta_{103} = 24.10$, $\log \beta_{111} = 17.50$, $\log \beta_{112} = 9.06$. $^b$ $p_q$, and $^c$ $p_{qr}$ reflect stoichiometric numbers of the fundamental components the complex species are composed of, as defined in the experimental section. $^d$ $p_{e} = \log \beta_{pq} - \log \beta_{pqr}$. $^e$ $\log K_2 = \log \beta_{102} - \log \beta_{111}$. $^f$ NP = number of points. $^g$ FP = fitting parameter representing an average deviation in cm$^{-1}$ between the experimental and fitted data for the full data set (including all evaluated titrations).

Complex formation processes start from pH $\sim$ 4.5 by the appearance of a protonated mono-complex ZnHL as reflected by the calculated species distributions (Fig. 6). A consecutive deprotonation process ZnHL $\rightarrow$ ZnL + H$^+$ leads to the formation of the parent complex ZnL where all of the dissociable protons of the peptide are already released. The $pK_a$ value for this process (= 5.95, see Table 2) is significantly lower than those attributed to the deprotonation processes of the HL and H$_2$L forms of the free ligand ($pK_{101} = 9.06$, $pK_{102} = 8.44$) and somewhat below the third $pK_a$ of HS ($pK_{101} = 6.60$). This strongly suggests that at least two, but potentially all the three neutral/basic donor groups of the ligand (histidine imidazole and two cysteine thiolates) are bound to ZnII in ZnL, whereas coordination of both cysteine and the histidine residues to the ZnII is also reflected in Table 2. The determined stability of ZnL ($\log K = 10.63$) reflects a remarkable affinity of HS to ZnII. This stability constant is, indeed, several orders of magnitude higher than those of the parent ZnII complexes of shorter peptides containing a CXH motif,$^{62}$ but also surpasses the stabilities of terminally protected tripeptides composed of a CXC sequence,$^{62}$ in spite of the substantially longer peptide chain and the larger distance between the two Cys residues in HS. Besides, HS has a notably higher affinity to ZnII compared to a similar 12-mer oligopeptide possessing no histidine residues (studied by us, $\log K = 9.93$).$^{50}$ Although higher stabilities were found for the ZnII complexes of some 10-mer peptides, all of these contained 2–3 histidines in addition to the two cysteine units.$^{63}$ Thus, the affinity of HS for ZnII falls in range that indicates the coordination of both histidine and the histidine residues to the
metal ion. The Zn\(^{II}\)-binding affinity of HS can also be demonstrated by the conditional stability calculated at pH 7.4 and 1:1 metal ion to ligand ratio based on the equations below,

\[
H_qL + Zn \rightleftharpoons ZnH_qL
\]

where Zn denotes the free Zn\(^{II}\) concentration while H\(_q\)L and ZnH\(_q\)L represent the overall concentration of the free and complexed ligands in any protonation states, respectively. The apparent stability constant for the above conditions is \(K_s = 7.5 \times 10^7\) (log \(K_s = 7.9\)) which is in the lower range of affinities reported for various wild-type bacterial Zn\(^{II}\)-regulators\(^{65}\) or variants.\(^{65}\)

The deprotonation of ZnL above pH 7.4 (Fig. 6A) leads to the species ZnH\(_{1-L}\) being strongly dominant under alkaline conditions. The observed extra deprotonation is most likely not a ligand-related proton release since the formation of a Zn\(^{II}\)-amide bond is a very scarce event in the complexes of Zn\(^{II}\) formed with terminally protected peptides.\(^{62,66-69}\) Accordingly, the ZnH\(_{1-L}\) composition may represent a species with a deprotonated water ligand, described as Zn(OH)L. The \(pK_a\) value of the deprotonation process is 8.65 that is ca. 1.7 log units lower than the \(pK_a\) determined for the same type of proton release of the Cd\(^{II}\) complex of HS,\(^{13}\) as expected, due to the smaller ionic radius of Zn\(^{II}\) as compared to Cd\(^{II}\). The deprotonation of the bound H\(_2\)O occurs also at a somewhat lower pH than in the ZnL complex of a similar ligand containing no His residue in position 3 of the peptide chain (\(pK_a = 9.11^{50}\)). The \{Zn(Cys)\(_2\)HisH\(_2\)O/OH\(^-\)\} coordination sphere is also found in horse liver alcohol dehydrogenase (LADH), where the \(pK_a\) of the metal ion bound water molecule is 9.2 for the native Zn\(^{II}\) containing enzyme,\(^{70}\) and 11.0 for the Cd\(^{II}\) substituted species.\(^{71}\) Interestingly, the \(pK_a\) of the Zn\(^{II}\)-bound water is lower in HS than in LADH. It seems that above neutral pH the histidine of HS significantly influences speciation, the coordination sphere of Zn\(^{II}\) and even the peptide structure, as indicated by UV and SRCD data.

Monomeric ZnHL and ZnL complexes dominate in the acidic/neutral pH-range when HS is present in a twofold excess over Zn\(^{II}\) (Fig. 6B). As indicated by UV data, metal-bridged bis-ligand species with different protonation states are also formed above pH \(\sim 6\). Although the determined stabilities of the various bis-complexes do not provide direct information on the binding mode of the ligands, the relatively high \(pK_a\) value for the ZnHL\(_2\) \(\rightarrow\) ZnL\(_2\) + H\(^+\) process (= 8.7, Table 2) suggests that there are protonated thiol groups in the ZnHL\(_2\) and ZnHL\(_2\) species. The stability constant calculated for the binding of the second ligand in ZnL\(_2\) (log \(K_s = 4.37\)) and the relative stability of the parent mono- and bis-complexes (log \(K_s(K_i/K_s) = 6.26\)) shows a notably weaker binding of the second ligand as compared to the same process in the Cd\(^{II}\) : HS system (log \(K_s(K_i/K_s) = 5.33^{13}\)) or to the Zn\(^{II}\)-binding of the above cited His-free peptide (log \(K_s(K_i/K_s) = 5.14^{10}\)). This finding provides a further support for the important role of histidine in controlling the interaction of Zn\(^{II}\) with HS.

\(^{1}\)H NMR experiments

Assignment of the \(^{1}\)H NMR resonances of HS and the pH-dependence of the recorded spectra in the absence of metal ions were published previously.\(^{13}\) Hg\(^{II}\) coordination to the peptide has a strong effect on the resonances of the Cys C\(_{\beta}\)H\(_2\) protons (Fig. 7). These signals shift from 2.93 ppm to relatively broad peaks at ~3.3–3.4 ppm (in an accidental overlap with one of the His C\(_{\beta}\)H\(_2\) resonances at pH 4.0–6.0) in the presence of one equivalent of Hg\(^{II}\). The significant, ca. 0.4 ppm down-field shift of the Cys C\(_{\beta}\)H\(_2\) resonances of the bound ligand, as compared to the same signals of the free HS indicates the binding of both thiolates to the metal ion, as also suggested by UV titrations.

Two separate signal sets of the Cys C\(_{\beta}\)H\(_2\) protons are observed at pH 4.0–6.0 when HS is in a twofold excess over Hg\(^{II}\) (Fig. 7). One set is reminiscent of the resonances of the free ligand, whereas the other coincides with those observed in the Hg\(^{II}\) : HS 1:1 system. Increasing pH to 8.0 results in coalescence of the two signal sets to a very broad bulge-like feature in the range of \(\delta \sim 2.8–3.4\) ppm overlapping with the His C\(_{\beta}\)H\(_2\) resonances (Fig. 7). This coalesced signal, with a chemical shift found in between those observed for Hg\(^{II}\) : HS...
The exchange rate, $k_{ex}$ between the bound and non-bound ligand forms may be roughly estimated from the observed line-broadening $^{73}$ at pH 4.0–6.0 which is dominated by slow exchange. The line-broadening, $w_e - w_0$, occurring for the Cys and His resonances of the free peptide due to the addition of 0.5 eq. Hg$^{II}$ is ca. 12 Hz which leads to $k_{ex} \sim \pi (w_e - w_0) \sim 38$ s$^{-1}$ at pH = 6.0 ($w_e$ and $w_0$ represent the line width of signals at half height with and without exchange, respectively). The calculation is based on the assumption of a two-site exchange of HS between a specific Hg$^{II}$-peptide bound form and the non-bound form under the applied experimental conditions. $k_{ex}$ may also be expressed by a formula involving the rates of the association and dissociation processes, as follows $^{73}$

$$k_{ex} = k_{on} [M] + k_{off} = \frac{k_{off}}{1 - f}$$

where $k_{on}$ and $k_{off}$ stands for the second order rate constant of the complex formation and the first order rate constant of the complex dissociation, respectively, $[M]$ is the concentration of the metal ion and $f$ represents the bound fraction of the ligand (0.5 in the present case). If one assumes that the association is diffusion controlled and thus $k_{on} \sim 7.4 \times 10^{9}$ M$^{-1}$ s$^{-1}$ that is the rate constant for diffusion controlled reactions in water at 298 K, $^{74}$ solving the above equation for $[M]$ would result in a concentration of [Hg$^{II}$] that corresponds to a $K_d$ $\sim 2.5 \times 10^{-9}$ M dissociation constant of the complex at pH = 6.0. This $K_d$ value suggests a many orders of magnitude weaker binding than expected for a typical {HgS$_2$} complex, $^{41}$ indicating that the picture is too simplistic, and presumably a more complex speciation occurs.

The increase of pH also induces the upfield shift of the resonances of the Asp (C$_3$H$_2$ – Fig. 7) and His (C$_4$H$_2$ – Fig. 7 and the C$_6$H and C$_8$H protons of the imidazole ring – Fig. 8) reflecting the deprotonation of the side chains of these residues. The chemical shift values are practically independent of the metal ion to ligand ratio at all selected pH values. These findings indicate that the proton releases from the Asp carboxyl groups and the His imidazole moiety are practically unaffected by the presence of Hg$^{II}$ and therefore that these groups do not participate in Hg$^{II}$-binding. Nevertheless, coordination of the cysteine residues to Hg$^{II}$ has a slight line
width increasing effect on the neighbouring Asp side chain resonances under acidic conditions (Fig. 7) and a rather pronounced impact on the His C$_\alpha$H and C$_\beta$H signals in neutral/alkaline solutions (Fig. 8). This shows that although the chemical shifts, apart from those of the cysteines, do not change significantly, the dynamics of the peptide is affected by the binding of Hg$^{II}$.

The spectra of HS obtained at pH $\sim$ 4.4 in the presence and absence of Zn$^{II}$ reflect no differences either in terms of the chemical shifts or the shape of the various H$^1$-resonances (Fig. S7). This suggests that, as opposed to Hg$^{II}$, Zn$^{II}$ is not bound to HS under such conditions, which is in agreement with the potentiometric and UV absorption studies, vide supra.

At pH $\sim$ 5.5, however, the presence of Zn$^{II}$ gives rise to pronounced broadening of most resonances. In the presence of 0.5 eq. Zn$^{II}$ this may indicate exchange between the bound and free states of the peptide, but in the fully loaded Zn$^{II}$:HS system it implies equilibria between conformers falling into the intermediate exchange time regime (ms–s) (Fig. 9–10). At a 1 : 1 ratio of Zn$^{II}$ and HS the C$_\alpha$H and C$_\beta$H signals of the His imidazole are shifted slightly upfield as compared to the resonances of the free ligand (Fig. 10). At 0.5 eq. of Zn$^{II}$ the chemical shifts of the imidazole ring protons appear in between those of the free HS and the 1 : 1 system reflecting an equilibrium between the non-bound and metal-bound peptide forms, and fast exchange dynamics for these resonances. The C$_\alpha$H and C$_\beta$H resonances are significantly shifted upfield by a further pH increase (pH 5.5 $\rightarrow$ 7.0), similarly to the metal ion free solution, which indicates that His-coordination is not completed at pH 5.5. A combined interpretation of the H$^1$ NMR, UV absorption, and potentiometric data at pH $\sim$ 5.5, (see Fig. 6) leads us to propose co-existing binding isomers of the ZnHL species, with the participation of two Cys-thiolates or one of the Cys-thiolates and the His side chain in metal ion binding.

The increase of pH to pH $\sim$ 7.0 gives rise to a substantial change of the spectral pattern. According to our data, all the metal ions are complexed under such conditions (Fig. 6). Most of the resonances, in addition to those of the Cys residues, display line broadening, in contrast to the signals observed for Hg$^{II}$:HS, where resonances from non-coordinating groups are not affected to the same extent. Thus, Zn$^{II}$-coordination affects the internal dynamics of the entire peptide on the NMR time scale. Additionally, the ligand exchange dynamics is slowed down to the moderately slow exchange time regime causing the splitting of several H$^1$ resonances (C$_\beta$H$_2$, C$_\epsilon$H and C$_\delta$H of His and all the resonances of Ile) into clearly distinguishable separate signals at a 0.5 : 1 Zn$^{II}$:HS ratio (see spectra at pH $\geq$ 7.0 on Fig. 9–10). The decrease of exchange rate by pH-increase coincides with a remarkable change of the CD-signals (Fig. 4), and occurs in parallel with the formation of the ZnL parent complex. It implies that the participation of several donor groups in metal ion binding leads to a reduced lability of species. At a 1 : 1 Zn$^{II}$:HS ratio, the C$_\beta$H$_2$ protons of the Cys and His residues experience a significant chemical shift change relative to the free ligand, as do the C$_\alpha$H and C$_\beta$H signals of the imidazole ring (Fig. 10). This supports the coordination of the two Cys-thiolates and the His-imidazolate groups to Zn$^{II}$ in ZnL, but the poorly resolved spectrum at pH = 7.0 does not provide information on the binding of Asp-carboxylates. As pointed out above, various resonances of the C-terminal Ile residue in the spectral region 0.8–1.0 ppm (C$_\beta$H$_2$, C$_\beta$H$_3$, C$_\gamma$H$_3$) are also strongly affected by metal ion coordination as those of the bound ligand are clearly shifted upfield compared to the ones of the free peptide-like resonances (Zn$^{II}$:HS 0.5 : 1, Fig. 9). Analogous spectral features were not observed in the systems of either Cd$^{II}$ and HS$^{13}$ or Zn$^{II}$ and a closely related peptide$^{50}$ differing only in the His-residue from the presently studied ligand. Thus, while the exact origin of the impact of Zn$^{II}$-binding on the Ile resonances is not clear, metal ion coordination of the histidine unit very likely plays a key role here.

Based on the observed line broadening of the Cys C$_\beta$H$_2$ protons at Zn$^{II}$:HS 0.5 : 1 (Fig. 9) a similar or slightly lower exchange rate between the bound and non-bound ligands, as compared to Hg$^{II}$:HS, may be predicted. However, the overlap of the various resonances and the complexity of the system (see the distribution curves at pH $\sim$ 7.0, Fig. 6b) do not allow a deeper discussion. It is, however, an interesting contrast to Hg$^{II}$:HS, that the exchange rate in the presence of Zn$^{II}$...
remain relatively slow even at higher pH (see below) approaching the deprotonation-range of the thiol groups of the free ligand. The increased metal ion exchange rate, as observed by the resonances of the Cys C\textsubscript{\textepsilon}H\textsubscript{\textdelta} protons (see Fig. 7) with 0.5 eq. Hg\textsuperscript{II} for pH above the pK\textsubscript{a} of the thiol, imply that the free thiolates take part in the exchange process, and thus that it occurs via an associative mechanism. The low coordination number may be important for this process, as it may allow for coordination of additional thiolates in the equatorial plane. This is analogous to a proposed mechanism of transfer of Cu\textsuperscript{I} between proteins,\textsuperscript{42,73,76} where the metal ion is also found in a structure with two thiolates coordinating. Contrary to this, the metal exchange rate does not change into the fast exchange regime with 0.5 eq. Zn\textsuperscript{II} for pH above the pK\textsubscript{a} for the thiol, see Fig. 9. This may reflect that the exchange occurs via a dissociative mechanism, although not necessarily via free Zn\textsuperscript{II}, in analogy to the common interpretation of ligand binding reactions for the Zn\textsuperscript{II} aqua ion involving dissociation of coordinated water as the rate determining step.\textsuperscript{77}

As a conclusion, and in line with SRCD data, the simultaneous binding of (at least) three side chain donors induces a more defined ligand structure in the Zn\textsuperscript{II}-bound HS, unlike the loop-like conformation proposed for Hg\textsuperscript{II}-bound HS.

At pH ~ 9.4 the spectra of the Zn\textsuperscript{II}-containing solutions are still very poorly resolved as the resonances are strongly broadened. Coordination of His to the metal ion in the Zn\textsuperscript{II} : HS 1 : 1 system is unambiguously demonstrated by the significant downfield shift of the C\textsubscript{\textepsilon}H and C\textsubscript{\textdelta}H resonances, as compared to the metal ion free sample (Fig. 10). A similar shift was observed and attributed to His-coordination in the Cd\textsuperscript{II}-complex of the peptide.\textsuperscript{13} At least three distinguishable, broad C\textsubscript{\textdelta}H peaks and three C\textsubscript{\textepsilon}H peaks, albeit less clearly, are observed at 0.5 : 1 Zn\textsuperscript{II} : peptide ratio (see the enlarged spectrum segments on Fig. 10). One of the C\textsubscript{\textepsilon}H\textsubscript{\textdelta}H and C\textsubscript{\textepsilon}H\textsubscript{\textdelta}H peaks appear very close to the free ligand-like signals while the third observed signals have chemical shifts resembling those measured for the 1 : 1 system. In order to elucidate the processes occurring in the presence of ligand excess above neutral pH, a more detailed series of spectra were recorded at pH ~ 8. One may follow the evolution of the C\textsubscript{\textepsilon}H and C\textsubscript{\textdelta}H signals from 0 : 1 to 1 : 1 Zn\textsuperscript{II} : peptide ratio on Fig. 11. The series describe the complete transformation of the non-bound ligand to the 1 : 1 species (mostly ZnL at this pH, see Fig. 6A). The spectra recorded at the intermediate stages, featuring the emergence and transformation of broad peaks, originate from a dynamic exchange between at least three coexisting species (see e.g. the C\textsubscript{\textepsilon}H\textsubscript{\textdelta}H resonances at a Zn\textsuperscript{II} : HS ratio of 0.75 : 1 or the C\textsubscript{\textepsilon}H\textsubscript{\textdelta}H resonances at a ratio of 0.5 : 1), the free peptide, the fully loaded Zn\textsuperscript{II}-peptide complex, and a species with a plausible 0.5 : 1 Zn\textsuperscript{II} : HS stoichiometry, i.e. a bis-ligand complex.

Fig. 10 Aromatic/H\textsubscript{\textdelta} region of the \textsuperscript{1}H NMR spectra of HS recorded in the absence of Zn\textsuperscript{II} and in the Zn\textsuperscript{II} : HS 0.5 : 1 and 1 : 1 systems (H\textsubscript{2}O/D\textsubscript{2}O = 90 : 10% v/v; c\textsubscript{HS} = 1.3 \times 10^{-3} M, T = 298 K). The open circle and square symbols show resonances of the non-bound ligand (C\textsubscript{\textepsilon}H and C\textsubscript{\textdelta}H, respectively) while the filled symbols mark the same resonances of the bound His residues in the mononuclear species. The regions of \( \delta = 6.9-7.15 \) and 7.4–8.05 ppm from the Zn\textsuperscript{II} : HS 0.5 : 1 spectrum at pH ~ 9.4 are magnified in the frames.

Fig. 11 Part of the \textsuperscript{1}H NMR spectra of HS recorded at pH ~ 8.0 as a function of the metal ion to peptide ratio (H\textsubscript{2}O/D\textsubscript{2}O = 90 : 10% v/v; c\textsubscript{HS} = 1.3 \times 10^{-3} M, T = 298 K). The selected regions reveal changes observed on the C\textsubscript{\textepsilon}H (left) and C\textsubscript{\textdelta}H (right) resonance of the His-imidazole moiety of the ligand. Note that the peak seen at \( \delta \sim 7.11 \) ppm on the free HS spectrum is one of the remaining amide resonances still observable at pH ~ 8.0.
This provides strong support for the potentiometric data. The species are in slow to intermediate exchange rate relative to the NMR timescale. The emerging signals in the range of $\delta \sim 7.0 - 7.08$ and $7.75 - 7.85$ ppm suggests that the His-imidazole moiety of at least one of the two ligands plays a role in Zn$^{II}$ coordination in some or all of the bis-complexes.

Only two sets of relatively sharp C$_s$H and C$_e$H resonances are detected at pH $\sim 11$ in the Zn$^{II}$: HS 0.5:1 system (Fig. 10) which is in excellent correlation with the equilibrium and UV results, i.e. the presence of only the ZnH$_{1L}$ complex and free ligand. Besides, the notable chemical shift changes observed on the spectra of Zn$^{II}$: HS 1:1 from pH $\sim 7.0$ up to 11.0 (see e.g. the range of $\delta \sim 3.5 - 2.5$ ppm (Fig. 9) or the C$_e$H signals (Fig. 10), clearly reflect the conversion of the ZnL parent complex to ZnH$_{1L}$.

Conclusion

The 12-mer HS peptide, inspired by the C-terminal metal ion binding domain of a bacterial metalloregulator CueR, is shown to efficiently bind Hg$^{II}$ and Zn$^{II}$, two metal ions with significantly different coordination preferences. Hg$^{II}$ is demonstrated to form a loop-like structure in a [HgS$_2$] coordination fashion via binding to the two cysteines of the ligand, but there is no sign for the participation of any other side chain donors in Hg$^{II}$-coordination. The kinetic lability of Hg$^{II}$ is manifested in line broadening on the $^1$H NMR spectra affecting mostly the resonances of the bound Cys residues and those of the neighbouring units. In contrast to Hg$^{II}$, Zn$^{II}$ dictates the peptide to a more structured form in its ZnL complex via binding to at least three side chain donors, the two Cys thiolates and the His imidazole. Indeed, the SRCD spectra above neutral pH might reflect an increasing helical content in the Zn$^{II}$-bound HS, although a contribution of the thiolate-metal ion chromophore to the observed CD-pattern may also be present in the same wavelength range. In addition to monomeric species, bis-ligand HS-Zn$^{II}$-HS complexes are also formed, unlike with Hg$^{II}$. The line broadening in $^1$H-NMR is pronounced for most of the resonances, indicating that exchange dynamics between different conformers occurs on the NMR time scale (ms–s) and that, in contrast to Hg$^{II}$, Zn$^{II}$, coordination notably affects the internal dynamics of the entire peptide chain. The results obtained demonstrate that the conformational and coordination flexibility allows HS to adopt diverse structures, favoured by different metal ions, which is a property that may be utilized for metal ion sequestration in practical applications. Experimental studies on the interaction of a flexible peptide like HS with metal ions are a challenge as speciation may be diverse and the system dynamic. In the span between coordination compounds to metalloproteins, dynamic systems like HS, may yield insight into the underlying mechanisms of metal ion exchange that are necessary to account for transport and distribution of essential trace elements in biological systems. In a more fundamental perspective, also the potential role of metal ions for protein folding (and misfolding) through transient binding may also be elucidated by interrogating such peptide–metal ion interactions.

Experimental

Materials

The investigated peptide N-acetyl-Ser-Cys-His-Gly-Asp-Glu-His-Asp-Cys-Ser-Ile-NH$_2$ (Ac-SCHGDQGSDCSI-NH$_2$, HS) was synthesized, as described earlier.$^{10}$ Chemicals and solvents were obtained from Sigma-Aldrich and used without further purification unless otherwise described. The solutions of Zn(ClO$_4$)$_2$$\cdot$6H$_2$O, Hg(OAc)$_2$ (Aldrich) were standardized complexometrically$^{78}$ while precise weights of high purity HgCl$_2$ (Aldrich) was used to prepare metal ion stock solutions. pH-Metric titrations were performed with NaOH (Aldrich) solutions standardized using potassium hydrogen phthalate (Sigma-Aldrich).

Electronic absorption and SRCD measurements

UV-Visible (UV-Vis) spectra were measured on a Shimadzu UV-3600 UV-VIS-NIR spectrophotometer using a cell with 1 cm optical pathlength. Concentration of the ligand was $1.0 \times 10^{-4}$ M and the metal ion concentration varied between $5.0 \times 10^{-5}$ and $2.0 \times 10^{-4}$ M.

The synchrotron radiation CD (SRCD) spectra of the free ligand and the metal complexes were recorded at the SRCD facility at the CD1 beamline on the storage ring ASTRID at the Institute for Storage Ring Facilities (ISA), University of Aarhus, Denmark.$^{79,80}$ All spectra were recorded with 1 nm steps and a dwell time of 2 s per step, using 0.1 mm quartz cells (SUPRASIL, Hellma GmbH, Germany), for the wavelength range of 175–260 nm. The substances were initially dissolved in 1.0 $\times$ 10$^{-2}$ M HCl in order to avoid the eventual oxidation process. The pH of the samples ($c_{\text{peptide}} = 1.0 \times 10^{-3}$ M) were adjusted by adding the appropriate amount of NaOH solution. From the raw spectra the water baseline was subtracted and spectra were normalized to $1.0 \times 10^{-3}$ M peptide concentration (to eliminate the effect of dilution).

Perturbed angular correlation of $\gamma$-rays

All perturbed angular correlation (PAC) experiments were performed in ISOLDE/CERN with a setup using six BaF$_2$ detectors keeping the samples at a temperature of 1 °C. Production and purification of the radioactive $^{199}$Hg is described in the literature.$^{81}$ The $^{199}$Hg solution (150 µL) was mixed with solutions of nonradioactive mercury(II) chloride, sodium perchlorate and buffer if needed. TRIS and CAPS buffers were used for adjusting the pH of samples to pH $\sim 8.0$ and 10, respectively. The peptide was dissolved in 0.01 M perchloric acid and amounts of this stock solution were added to the buffered Hg$^{II}$-containing solutions to reach the desired final concentrations. Finally, sucrose was added to 55% w/w. The pH of the solutions was adjusted with NaOH and HClO$_4$. In order to avoid contamination of the samples, small volumes were taken for pH...
measurements. The temperature dependence of the pH in the TRIS/CAPS-buffered solutions was taken into account and pH-values were corrected to 1 °C.82 The buffers and the peptide stock solutions were purged with argon. The final volume of the samples was 210 μL with $c_{\text{peptide}} = c_{\text{H}_2\text{O}} = 8.03 \times 10^{-5} \text{ M}$ and $c_{\text{buffer}} = 1.60 \times 10^{-2} \text{ M}$.

NMR experiments

$^1$H NMR measurements were performed on a Bruker Avance DRX 500 spectrometer operating at 500.132 MHz. The spectra were recorded at $T = 298 \text{ K}$ in a mixture of H$_2$O/D$_2$O = 90 : 10% v/v and in a few cases in pure D$_2$O applying the zgpr or zgcppr pulse sequences in order to presaturate the H$_2$O/HDO resonances. In a typical sample the concentration of the peptide was $1.3 \times 10^{-3} \text{ M}$. The chemical shifts were referenced to TSP-$d_4$ at 0.0 ppm. Spectra were recorded using a recycle delay of 5 s, an acquisition time of 1.64 s, a spectral width of 5 or 10 kHz and 64–128 scans. In D$_2$O, the pH$^+$ ($\text{pH}$-meter reading uncorrected by the deuterium effect) was adjusted to the desired values with NaOD. The recorded spectra were processed by the ACD/Spectrus Processor software.83

pH-Potentiometric measurements

The protonation and coordination equilibria were investigated in aqueous solutions ($I = 0.1 \text{ M NaClO}_4$ and $T = 298.0 \pm 0.1 \text{ K}$) under argon atmosphere with a special care to avoid the oxidation of the peptide. The potentiometric titrations were carried out by an automatic titration set including a PC controlled Dosimat 665 (Metrohm) autoburette, an Orion 710A precision digital pH-meter equipped with an Orion 8103BNWP Ross Ultra semi micro pH electrode (165 × 6 mm). Conversion of the relative mV values as pH-meter readings corrected by the deuterium excess in alkaline pH-range, titration data for the Zn$^{II}$ : HS 2 : 1 samples were evaluated only up to pH 7.1. (The individual fitting parameter of titrations performed with ligand excess dropped by ca. 40% when considering differently protonated bis-ligand species (ZnH$_2$L$_2$) besides monomeric ones, and accordingly such species were also included in the final model.
