Hydrogen gas is emerging as an attractive fuel with high energy density for the direction of energy resources in the future. Designing integrated devices based on a photoelectrochemical (PEC) cell and a microbial fuel cell (MFC) represents a promising strategy to produce hydrogen fuel at a low price. In this work, we demonstrate a new solar-microbial (PEC–MFC) hybrid device based on the oxygen-deficient Nb2O5 nanoporous (Nb2O5x NPs) anodes for sustainable hydrogen generation without external bias for the first time. Owing to the improved conductivity and porous structure, the as-prepared Nb2O5x NPs film yields a remarkable photocurrent density of 0.9 mA cm⁻² at 0.6 V (vs. SCE) in 1 M KOH aqueous solution under light irradiation, and can achieve a maximum power density of 1196 mW m⁻² when used as an anode in a MFC device. More importantly, a solar-microbial hybrid system by combining a PEC cell with a MFC is designed, in which the Nb2O5x NPs electrodes function as both anodes. The as-fabricated PEC–MFC hybrid device can simultaneously realize electricity and hydrogen using organic matter and solar light at zero external bias. This novel design and attempt might provide guidance for other materials to convert and store energy.

1. Introduction

The rational utilization of renewable and clean energy has drawn more and more attention due to the increasing energy demands and ever-growing environmental concerns. Producing hydrogen by photoelectrochemical (PEC) water splitting over a semiconductor photoelectrode is emerging as the most promising way that can directly convert solar energy into clean hydrogen.1,2 Hydrogen from water splitting is known to be a thermodynamically uphill or endothermic process and can be described as the following equation:

\[
\text{H}_2\text{O(l)} \rightarrow \text{H}_2(g) + 1/2\text{O}_2(g), \quad \text{E}^0 = 1.23 \text{ V vs. NHE}
\]  

(1)

To drive this reaction, a minimal energy of 237.2 kJ mol⁻¹ that is equal to a potential of 1.23 V vs. NHE is required.2,3 In this respect, it requires the conduction band (CB) and valence band (VB) edges of the photoelectrode to straddle the reduction and oxidation potentials of water. Specifically, \( E_{\text{CB}} \) should be above \( E_{\text{red}} (\text{H}_2/\text{H}^+ ) \) and \( E_{\text{VB}} \) should be below \( E_{\text{ox}} (\text{OH}^-/\text{O}_2) \). Besides having suitable band edge positions, an ideal photoelectrode material for efficient solar water splitting should also possess strong light-harvesting ability, good chemical stability, fast charge transport and low cost.4-6 However, most of the developed photoelectrodes cannot satisfy these requirements simultaneously. On the other hand, an external bias is always needed for practical applications to improve their charge separation and/or overcome an overpotential for the low lying CB edge, which leads to increased cost of hydrogen production.7-10 In order to address the above-mentioned energy loss, numerous efforts have been devoted to designing nano-structured photoelectrodes and catalysts as well as optimizing the PEC configuration.11-13 Nevertheless, the current efficiency of PEC water splitting is still not satisfactory for its high energy demand.14-15 Alternatively, the energy required for water splitting obtained from a renewable energy source is a more cost-effective approach to generate hydrogen.

Microbial fuel cells (MFCs) are of great interest since they can directly produce electricity from organic waste and biomass at a low cost. MFCs are bioelectrochemical devices that can convert chemical energy stored in organic matter into electricity with the help of microorganisms.16-22 This feature makes them very attractive as a green energy supply to overcome the thermodynamic constraints and compensate for the energy loss of PEC water splitting. Recently, Wang et al. demonstrated that the hydrogen gas could be continuously produced based on solar
light and biomass recycling through coupling PEC water splitting with a TiO$_2$ nanowire-arrayed photoanode and microbial electrohydrogenesis with *Shewanella oneidensis* MR-1 in a PEC-MFC hybrid device.$^{18}$ Despite these achievements, the unsatisfactory performances of the current MFCs and PEC cells are the main obstacles for their practical applications. The electrode material is the most key factor that determines the performances of both the MFCs and PEC cells.$^{16,19,24-27}$ Therefore, the exploration and development of an advanced electrode material for improving the efficiency of PEC cells and the output power density of the MFCs are highly desirable.

In this work, we demonstrate the feasibility of oxygen-deficient Nb$_2$O$_5$ nanoporous (Nb$_2$O$_{5-x}$ NPs) films as a high-performance anode material for both the PEC and MFCs. Nb$_2$O$_5$ is one of the most important n-type semiconductor materials for dye-sensitized solar cells and photocatalysts in terms of its excellent photoactivity, non-toxicity and environmental friendliness.$^{28-31}$ It has a similar bandgap to TiO$_2$ and ZnO, and favourable band-edge positions that can straddle the redox potential of water photoelectrolysis. Moreover, recent reports have shown that Nb$_2$O$_5$ possesses better biocompatibility than TiO$_2$ and higher stability than ZnO (amphoteric oxide).$^{34,35}$ All of these characteristic features make it a very promising photoanode and anode for PEC and MFCs, respectively. However, Nb$_2$O$_5$ suffers from poor electrical conductivity, which seriously limits its wide applications. Herein, we developed a facile approach to significantly boost the conductivity of Nb$_2$O$_5$ by creating oxygen vacancies. Nb$_2$O$_{5-x}$ NPs films were readily obtained by anodic oxidation of Nb foil and hydrogenation treatment. Benefiting from the appropriate bandgap, suitable band levels, improved conductivity and good biocompatibility, the Nb$_2$O$_{5-x}$ NPs films exhibited superior performances in both the PEC cells and MFCs. The Nb$_2$O$_{5-x}$ photoanode achieved a remarkable photocurrent density of 0.9 mA cm$^{-2}$ at 0.6 V (vs. SCE) in 1 M KOH aqueous solution, and the MFCs with the Nb$_2$O$_{5-x}$ NPs anodes (denoted as Nb$_2$O$_{5-x}$MFCs) exhibited a maximum power density of 1196 mW m$^{-2}$. More Interestingly, a PEC-MFC hybrid device, by interfacing a Nb$_2$O$_{5-x}$-based PEC device and a Nb$_2$O$_{5-x}$-based MFC device, was designed and continuous hydrogen gas could be produced at zero external bias by biodegradable organic matter and solar light.

2. Experimental section

2.1 Fabrication of Nb$_2$O$_5$ and Nb$_2$O$_{5-x}$ NPs films

Nb$_2$O$_5$ NPs films were synthesized by the simple electrochemical anodization of Nb films. Before the anodization, the Nb film was washed by ultrasonication in acetone, ethanol and then deionized water successively. The Nb film was anodized at an applied potential of 20 V for 30 min at room temperature, with the Nb film as the working electrode and a graphite rod of about 4.0 cm$^2$ as the cathode in a glycerol aqueous solution (90 vol% glycerol : 10 vol% H$_2$O) containing 1.5% NH$_4$F. The as-prepared Nb$_2$O$_5$ NPs films were cleaned with ethanol and DI water, and then were annealed at 450 °C for 60 min in air to enhance the mechanical stability and crystallinity. Finally, the Nb$_2$O$_{5-x}$ NPs films were obtained by annealing the Nb$_2$O$_5$ NPs films in a hydrogen atmosphere at various temperatures ranging from 450–550 °C for 60 min. Thermal treatment was performed in a home-built tube furnace filled with ultrahigh purity hydrogen gas.

2.2 Fabrication of MFC

At first, *E. coli* K-12 (ATCC 25922) was cultured at 37 °C in a fertile medium (a mixture of 10.0 peptone, 5.0 g NaCl and 3.0 g beef powder per liter) in an anaerobic test tube, which was sterilized at 121 °C in an autoclave for 20 min in advance. Secondly, 10 mL of the *E. coli* K-12 culture medium was inoculated into the nitrogen saturated anolyte, after growing for 18 h in the incubator. A cubic MFC with a single chamber (4 cm × 5 cm × 5 cm) was used in this work, which consists of a poly-methyl methacrylate chamber and a membrane cathode assembly on one side (4 cm × 4 cm). The sample electrodes (4 cm × 4 cm) were directly used as the anodes. The cathode was prepared by hot-pressing carbon paper on one side of a cation exchange membrane (CEM). The carbon paper cathode was pasted with 12.5 mg cm$^{-2}$ commercial Pt catalyst (40 wt% Pt/C) in a mixture of Nafton (5%). Phosphate-buffered basal medium (PBBM) with 5 mM HNQ, 10.0 g glucose and 5.0 g yeast extract per liter was used as the anolyte. The PBBM consisted of 8 g NaCl, 0.2 g KCl, 3.63 g Na$_2$HPO$_4$·12H$_2$O, and 0.24 g KH$_2$PO$_4$ per litre. To remove the possible metal and biomass contamination, the cell was washed with 1 mol L$^{-1}$ HCl and 1 mol L$^{-1}$ NaOH and rinsed with sterile water before the inoculation.

2.3 Material characterization

The surface structure, morphology and composition of the samples were characterized by scanning electron microscopy (SEM, Quanta 400), X-ray diffraction (XRD, Bruker, D8 ADVANCE) with Cu Kz radiation ($\lambda = 1.5418$ Å), and transmission electron microscopy (TEM, JEM2010-HR). X-Ray Photoelectron Spectroscopy (XPS, ESCALab250) with 200 W Al Kz radiation was used to measure the chemical bonding state and chemical state of the samples. The C 1s peak at 284.8 eV from adventitious carbon was regarded as the energy reference. Raman spectroscopy was conducted on a Laser Micro-Raman Spectrometer (Renishaw inVia) using a visible laser ($\lambda = 514.5$ nm) with an output laser power of 50 mW as the excitation wavelength at room temperature. The optical properties of the products were measured with a UV-Vis-NIR spectrophotometer (UV, Shimadzu UV-3150). EPR spectra were studied on powdered products by a conventional Bruker spectrometer (Bruker, A300-10-12) operating at an X-band frequency and magnetic field modulation of 100 kHz, with a microwave power of 2.23 mW and a modulation amplitude of 8 G at 88 K. The resonance lines were simulated by the Bruker WINEPR SimFonia program.

2.4 Photoelectrochemical and electrochemical measurements

PEC measurements were carried out in a three-electrode cell with a flat quartz window to facilitate illumination of the photoelectrode surface. The Pt foil electrode and a saturated
calomel electrode were used as the counter and reference electrode, respectively. A 1.0 M NaOH aqueous solution was used as the electrolyte, and the illumination source was a 150 W xenon lamp coupled with an AM 1.5G filter. Additionally, a 1.0 M NaOH aqueous solution with 10.0 g glucose per liter was used in the control experiment. Incident photon to current conversion efficiencies (IPCE) were collected by a CHI 760D electrochemical station with a solar simulator (Newport 69920, 1000 W xenon lamp), coupled with an infrared water filter (Oriel 6127) and aligned monochromator (Oriel Cornerstone 130 1/8 m). To quantitatively reveal the interplay between the photoactivity and light absorption, incident photon to current conversion efficiencies (IPCE) were measured on the Nb2O5 and Nb2O5-x NPs photoanodes at 0.2 V vs. SCE. IPCE can be expressed by the equation:

$$\text{IPCE} = \frac{(\lambda J_{\text{light}})}{J_{\text{dark}}}$$

where \(\lambda\) is the measured photocurrent density at a specific wavelength, \(\lambda\) is the wavelength of incident light, and \(J_{\text{light}}\) is the measured irradiance at a specific wavelength. The conductivity of the as-prepared films is measured by two-point current–potential \((I-V)\) curves by a typical two electrode system. One of the electrodes is fixed on the substrate and the other fixed on the surface of the film. All of the process is completed with silver paste and under the same conditions.

3. Results and discussion

3.1 Synthesis and characterization of Nb2O5-x NPs films

Nb2O5-x NPs films were obtained through a two-step procedure, which involves the anodic oxidation of Nb foil and heat treatment in a hydrogen atmosphere. Firstly, the Nb2O5 NPs films were synthesized on a niobium film substrate by a simple anodic oxidation method and annealed in air at 450 °C (Experimental section). The SEM images show that the white homogeneous film obtained on the metal substrate is composed of dense nanoporous arrays with ~50 nm diameter (Fig. S1, ESI†). To introduce oxygen vacancies into the Nb2O5 NPs films, the as-prepared Nb2O5 NPs films were then annealed in a hydrogen atmosphere for an additional 60 min at 500 °C. The synthetic process of the hydrogen treatment is illustrated in Fig. 1a. After the treatment, the film color changed from white to blue (Fig. S2, ESI†), suggesting a possible modification in the crystal structure. To identify the possible phase transformation, XRD patterns of the Nb2O5 and Nb2O5-x NPs films are shown in Fig. 1b. Sharp diffraction peaks centered at 2θ angles of 22.6°, 28.4° and 50.8°, corresponding to the (001), (180) and (0 16 0) planes of Nb2O5 (JCPDS #30-0873), are observed for both samples, indicating that the NPs films are well crystalline with a similar phase. SEM studies also reveal there are no obvious morphological changes for the Nb2O5-x NPs film after the hydrogenation (Fig. 1c). Fig. 1d displays the TEM image and the selected-area electron diffraction (SAED) of the Nb2O5-x NPs film. The TEM image obviously shows that the porous Nb2O5-x sample consists of the nanoporous arrays. The clear lattice fringes with a spacing of 0.39 nm are indexed to the (001) plane of the orthorhombic Nb2O5 samples. Meanwhile, the bright and well-arranged diffraction spots further confirm the highly crystalline nature of the Nb2O5-x NPs film.

The UV-visible absorption spectra of Nb2O5 and Nb2O5-x NPs films were collected to investigate the influence of hydrogenation on the optical absorption (Fig. S2, ESI†). Both of the samples exhibit similar light absorption in the UV region and the Nb2O5-x NPs film shows substantially higher absorption when compared to pristine Nb2O5 in the region of 400–800 nm, which suggests Nb2O5-x may absorb more visible light. The band gap of the Nb2O5-x NPs film is calculated to be 3.26 eV, while it is 3.35 eV for the pristine Nb2O5 NPs film, indicating the hydrogenation has a negligible effect on its band gap. To further investigate the effect of the hydrogen treatment on the chemical state of Nb2O5-x, XPS analysis was performed. The XPS survey of the Nb2O5-x NPs film was collected to prove that no other impurities were introduced after the hydrogen treatment (Fig. S3, ESI†). Fig. 1e displays the normalized high resolution Nb 3d core level XPS spectra. Both of the samples have two peaks located at 207.3 and 210 eV, which are ascribed to the regular Nb 3d signals for Nb5+. Remarkably, the Nb2O5-x NPs film displays an additional peak which emerged at the lower binding energy of 205.9 eV, which is the typical peak position for the low charge Nb4+. The presence of Nb4+ in the Nb2O5-x NPs film also had been regarded as the reason why the film’s colour changed from white to blue after the hydrogenation (Fig. S2, ESI†).†44-45 Fig. 2a compares the normalized O 1s core level XPS spectra of the Nb2O5 and Nb2O5-x NPs samples. Significantly, the Nb2O5-x NPs film shows a broader peak at around 531.68 eV than that of the Nb2O5 NPs film, indicating it has more oxygen vacancies than the Nb2O5 NPs film.44,46 This is also confirmed by the electron paramagnetic resonance (EPR) analysis. The broader peaks at \(g = 2.15\) and 2.02 in Fig. 2b clearly reveal the density of oxygen vacancies in the Nb2O5-x NPs film is much higher than that in the Nb2O5 NPs film.49,50

Electrochemical impedance measurements were carried out to verify our hypothesis that the induced oxygen vacancy can serve as a shallow donor to increase the carrier density of Nb2O5. Fig. 3a displays the Mott–Schottky plots of the electrodes at a frequency of 1 kHz in the dark, which are generated based on capacitances that derived from the electrochemical impedance. Both the Nb2O5 and Nb2O5-x NPs films show positive slopes, in line with the characteristic of a n-type semiconductor. Notably, the Nb2O5-x NPs film shows a substantially smaller slope for the Mott-Schottky plot than the Nb2O5 NPs film, suggesting a significantly increased donor density, based on the following equation:

\[N_d = (2e_0\varepsilon_0\varepsilon)V/(d(1/C^2)\mathrm{d}V)^{-1}\]

where \(N_d\) is the donor density, \(e_0\) is the electron charge, \(\varepsilon\) is the dielectric constant of Nb2O5 (\(\varepsilon = 41\)), \(e_0\) is the permittivity of vacuum, and \(V\) is the applied bias at the electrode.41 The carrier densities of the Nb2O5 and Nb2O5-x samples are calculated to be \(1.45 \times 10^{18}\) and \(3.68 \times 10^{21} \, \text{cm}^{-3}\), respectively. It should be noted that here we used the electrode area instead of the surface area of the nanoporous film for the calculation, which may
cause errors in determining the carrier densities. However, a qualitative comparison of the carrier densities between the Nb$_2$O$_5$ and Nb$_2$O$_5$/Co NPs samples is reliable, since they have a similar morphology and surface area. Obviously, the Nb$_2$O$_5$/Co NPs film possesses a 5 order of magnitude improvement on the donor density compared to the Nb$_2$O$_5$ NPs film, which results in a significant facilitation of the charge separation in the Nb$_2$O$_{5-x}$ NPs film. Meanwhile, the $I$–$V$ curves of the Nb$_2$O$_5$ and Nb$_2$O$_{5-x}$ NPs samples at room temperature were also collected in Fig. 3b. As expected, the electrical conductivity of the Nb$_2$O$_5$ sample is substantially improved after hydrogenation. All of these results validly confirm that the introduced oxygen vacancies can remarkably enhance the donor density as well as the conductivity of the Nb$_2$O$_5$ NPs film.

### 3.2 Performances of PEC devices based on Nb$_2$O$_{5-x}$ photoanodes

The PEC performances of the Nb$_2$O$_5$ samples were measured in a three electrode electrochemical cell with a 1.0 M NaOH solution as the electrolyte. For optimizing the PEC performance of the Nb$_2$O$_{5-x}$ NPs film, the effect of the hydrogenation
temperature was studied. Fig. 4a shows the linear sweep curves (LSV) of the pristine Nb2O5 and Nb2O5–x NPs films obtained at different hydrogenation temperatures. The photocurrent density of the Nb2O5 NPs film is 0.05 mA cm$^{-2}$ at 0.6 V vs. SCE, which is close to the value reported previously. The photocurrent densities of the Nb2O5–x NPs films increase gradually with the increase of the hydrogen treatment temperature from 450 to 500 °C. The Nb2O5–x (500 °C) NPs film achieves a maximum value of 0.9 mA cm$^{-2}$ at 0.6 V vs. SCE, which is about a 20-fold enhancement compared to the Nb2O5 NPs film at the same potential. This photocurrent density is also dramatically higher than the values recently reported for the reported values of Nb2O5 photoanodes, such as N-doped Nb2O5 nanostructures (Table S1)$^{36,51-53}$ Photocurrent densities decrease gradually with the rising temperature when the annealing temperature is above 500 °C. According to the increasing donor density and conductivity of the Nb2O5–x with the rising hydrogenation temperature (Fig. S4, ESI†), it can be concluded that excessive oxygen vacancies will serve as recombination centres for electrons and holes, resulting in a poor PEC performance, in agreement with other work.$^{54}$ To quantitate the interplay between the photoactivity and light absorption, incident photon to current conversion efficiencies (IPCE) were measured for the Nb2O5 and Nb2O5–x NPs photoanodes at 0.2 V vs. SCE (Fig. 4b). All of the Nb2O5–x NPs films show significantly enhanced photoactivity over the entire UV region, and the Nb2O5–x NPs film hydrogenated at 500 °C exhibits the best IPCE efficiency in the wavelength range from 300 to 380 nm. Additionally, the IPCE values decrease from 35% at 300 nm to 1% at 400 nm, and we did not observe any photoactivity in the visible light region beyond 400 nm, indicating that the observed colour change is not because of the band gap modification of Nb2O5 or the transition between the impurity states and conduction/valence band edges.$^{55}$ Thus, we believe that the photoactivity enhancement of the Nb2O5–x NPs film is because of the increased donor density and conductivity originating from the induced oxygen vacancies generated during the hydrogenation.

3.3 Performances of the MFC devices based on Nb2O5–x anodes

To demonstrate that the as-prepared Nb2O5–x NPs film is also a promising candidate as a high-performance anode material for a MFC device, a simple MFC device was assembled using the Nb2O5–x NPs film hydrogenated at 500 °C as the anode and a 40 wt% Pt/C loaded carbon paper as the air cathode in the E. coli MFCs (denoted as Nb2O5–x-MFC, Experimental section). For a better comparison, the performance of the pristine Nb2O5 NPs film in the MFC device was also measured (denoted as Nb2O5-MFC). Fig. 5a and b depict the comparison of the polarization curves and power outputs tested by loading various external resistances. In comparison to the Nb2O5-MFC, the cell voltage of the Nb2O5–x-MFC decreased more slowly with the decreased loaded resistance and gently, indicating the superior performance of the Nb2O5–x NPs anode. Furthermore, the Nb2O5–x-MFC achieved a remarkable maximum power density of 1196 mW m$^{-2}$ at a current density of 4465 mA m$^{-2}$, which is substantially higher than that of the Nb2O5-MFC (140 mW m$^{-2}$).

The distinct enhancement between the Nb2O5 and Nb2O5–x MFC devices can be ascribed to the superior conductivity of the Nb2O5–x NPs anode. Additionally, without E. coli, the Nb2O5–x-MFC device shows negligible cell voltage and output power density when loading the external resistances (Fig. S5†), indicating E. coli is very important for power production.

3.4 Performances of PEC–MFC hybrid devices based on Nb2O5–x anodes

For taking full advantage of the oxygen-deficient electrodes, we assembled a PEC–MFC hybrid device to convert and store energy using the Nb2O5–x NPs film as the anode in both the MFC and the PEC cell (Experimental section). The PEC properties of Nb2O5–x NPs film were measured in a two-electrode electrochemical cell with/without the MFC devices in the dark and under 1 sun illumination. Fig. 6a shows the schematic configuration of the integrated PEC–MFC hybrid device. By coupling the PEC and MFC devices in series, the Nb2O5–x anode in the MFC provides a biovoltage that shifted the potential of the illuminated Nb2O5–x photoanode near to −0.6 V, thus,
enabling water splitting to occur at zero external bias (Fig. 6b). The PEC–MFC device displays a novel photocurrent density of 0.18 mA cm\(^{-2}\) at zero bias (0 V vs. Pt), which is substantially larger than the one obtained from the PEC cell alone at the same potential (Fig. 6b). More importantly, gas bubbles were clearly observed to be continuously evolving on the Pt electrode under light illumination (Fig. 6c), implying the hybrid device is feasible to produce hydrogen. To the best of our knowledge, this is the first demonstration of using PEC–MFC hybrid devices based on the same anode material to generate hydrogen at zero external bias.

4. Conclusions

In summary, we developed a facile and effective method to significantly improve the conductivity and performances of the Nb\(_2\)O\(_5\)–x NPs films in PEC cells and MFCs through the introduction of oxygen vacancies. The Nb\(_2\)O\(_5\)–x NPs photoanode achieved a remarkable photocurrent density of 0.9 mA cm\(^{-2}\) at 0.6 V (vs. SCE) in a 1 M KOH aqueous solution. Meanwhile, the Nb\(_2\)O\(_5\)–x/MFC exhibited a superior power density of 1196 mW cm\(^{-2}\) when the Nb\(_2\)O\(_5\)–x NPs film was used as an anode in the MFC cell. The oxygen vacancy plays a critical role in enhancing the effective charge transport of the electrodes, as well as increasing the conductivity. Moreover, we also demonstrated that the PEC–MFC hybrid device with the Nb\(_2\)O\(_5\)–x NPs anodes in both devices is feasible and could produce hydrogen even at zero external bias (0 V vs. Pt) under illumination. To our best knowledge, it is the first report about the applications of Nb\(_2\)O\(_5\) materials in an integrated PEC–MFC device to produce hydrogen without an external bias, by just using organic matter and solar light. This environmentally friendly and novel design provides a promising research direction for the future development of energy conversion and storage.
