Relationships between elastic anisotropy and thermal expansion in A$_2$M$_3$O$_{12}$ materials†

Carl P. Romao,$^{a,b}$ S. P. Donegan,$^{b,c}$ J. W. Zwanziger$^{a,d,e}$ and Mary Anne White$^{a,d,e}$

We report calculated elastic tensors, axial Grüniesen parameters, and thermal stress distributions in Al$_2$Mo$_3$O$_{12}$, ZrMgMo$_3$O$_{12}$, Sc$_2$Mo$_3$O$_{12}$, and Y$_2$Mo$_3$O$_{12}$, a series of isomorphic materials for which the coefficients of thermal expansion range from low-positive to negative. Thermal stress in polycrystalline materials arises from interactions between thermal expansion and mechanical properties, and both can be highly anisotropic. Thermal expansion anisotropy was found to be correlated with elastic anisotropy: axes with negative thermal expansion were less compliant. Calculations of axial Grüniesen parameters revealed that the thermal expansion anisotropy in these materials is in part due to the Poisson effect. Models of thermal stress due to thermal expansion anisotropy in polycrystals following cooling showed thermal stresses of sufficient magnitude to cause microcracking in all cases. The thermal expansion anisotropy was found to couple to elastic anisotropy, decreasing the bulk coefficient of thermal expansion and leading to lognormal extremes of the thermal stress distributions.

Introduction

Materials with the general formula A$_2$M$_3$O$_{12}$, where A is a trivalent cation and M is W or Mo, have the unusual property of linear coefficients of thermal expansion spanning the range from low positive ($2.4 \times 10^{-6}$ K$^{-1}$) to negative ($-9 \times 10^{-6}$ K$^{-1}$), including zero.$^{5-9}$ Their structures have considerable chemical flexibility, as solid solutions can be made incorporating cations with large differences in size (e.g., Al$^{3+}$ and Y$^{3+}$).$^{3}$ Aliovalent substitutions of Zr$^{4+}$ or Hf$^{4+}$ with Mg$^{2+}$ for A$^{3+}$ can be performed, offering additional possibilities for the tailoring of physical properties within this family.$^{5-8}$ The structures of these materials are composed of vertex-linked networks of AO$_6$ octahedra and MO$_4$ tetrahedra; negative contributions to thermal expansion arise from transverse motions of bridging oxygen atoms accompanied by distortion of the AO$_6$ octahedra.$^{9,12}$ Negative thermal expansion (NTE) has been correlated with the compliance of the A-O ionic bond, and the subsequent distortability of the AO$_6$ octahedra.$^{5,9,12}$ The open-framework structure allows for unusual thermal expansion and chemical flexibility,$^{4,12,13}$ and it typically leads to low stiffness in comparison to other oxide ceramics.$^{5,14-17}$

The thermal expansion of materials from the A$_2$M$_3$O$_{12}$ family is known to be highly anisotropic.$^{15,18}$ Such anisotropy can cause large thermal stresses and subsequent microcracks in polycrystalline materials with randomly oriented grains.$^{19,20}$ However, the elastic anisotropy of these materials is generally unknown; furthermore, it is more difficult to determine experimentally than the anisotropy of the coefficient of thermal expansion (CTE). Critically, the mechanical properties determine the ability of thermomiotic (negative thermal expansion)$^{15}$ materials to counteract positive thermal expansion$^{15,21}$ and affect the stress distributions in polycrystalline A$_2$M$_3$O$_{12}$ materials.$^{15}$ Therefore, the elastic tensors of Al$_2$Mo$_3$O$_{12}$, Sc$_2$Mo$_3$O$_{12}$, and ZrMgMo$_3$O$_{12}$ have been calculated and reported herein. Together with that of Y$_2$Mo$_3$O$_{12}$ (reported previously)$^{16}$ we now have elastic constants of an isomorphic family of materials ranging from low positive to large negative thermal expansion.

The study of the anisotropy of the elastic properties of these materials generally has previously been limited to determination of bulk moduli by variable-pressure XRD; the exception is Y$_2$Mo$_3$O$_{12}$. The variable-pressure XRD experiment can yield information about directional compressibilities; for example in Sc$_2$W$_2$O$_{12}$ and Sc$_2$Mo$_3$O$_{12}$ the compressibility along an axis was shown to be positively correlated with the thermal expansion along that axis. However, this technique has limitations; for example the compressibilities in orthorhombic Al$_2$W$_2$O$_{12}$ could not be accurately determined due to a pressure-induced phase transition,$^{14}$ and no information about shear elasticity was obtained. The use of ultrasonic measurement to obtain
shear moduli of bulk polycrystalline samples\(^5\)\(^,\)\(^16\)\(^,\)\(^21\) contributes some additional information, but experimental determination of the full elastic tensor would require single crystals for Brillouin spectroscopy or resonant ultrasound spectroscopy.

Therefore, for practical reasons, computational methods are the best choice to study the full elastic anisotropy of \(A_2M_3O_{12}\) materials, and this is the approach taken herein. There is an associated drawback: the DFT calculations are performed for \(T = 0\) K. Since \(A_2M_3O_{12}\) materials (except \(Y_2M_3O_{12}\)) transition to a monoclinic phase upon cooling, the calculations were performed on a phase which is not stable at absolute zero. Therefore the phononic structures contain vibrational modes with negative energy that destabilize the orthorhombic structure.\(^22\)\(^\text{-}\)\(^24\)

However, since the orthorhombic–monoclinic phase transition involves rotation of the coordination polyhedra,\(^7\) the unstable mode is located away from the \(\Gamma\) point of the Brillouin zone\(^25\)\(^,\)\(^26\) and the instability is not caused by negative terms in the elastic stiffness tensor.\(^27\) Additionally, because many thermomaterials have highly temperature-dependent bulk moduli\(^18\)\(^,\)\(^28\)\(^-\)\(^30\) DFT results will not necessarily match room-temperature elastic constants, but our approach is validated by comparison with experimental behaviour at room temperature.

The energies of the optic phonons at the \(\Gamma\) point were also calculated using DFT. Calculation of the full dispersion relationship would be computationally expensive, however with the large unit cell of the orthorhombic \(A_2M_3O_{12}\) materials (68 atoms)\(^1\)\(^,\)\(^5\) there is little dispersion.\(^16\)\(^,\)\(^18\) Low-energy optic phonon modes in \(A_2M_3O_{12}\) materials corresponding to polyedral distortions can have large negative Grüneisen parameters,\(^31\)\(^,\)\(^32\) and therefore their energies play an important role in the thermal expansion behaviour. Determination of optic phonon frequencies also allows further validation of the calculations by comparison to experimental Raman spectra.

### Methods

DFT calculations were carried out using the ABINIT\(^33\) code in order to determine the elastic tensors and \(\Gamma\)-point phonon energy of \(A_2M_3O_{12}\) and \(AMgM_3O_{12}\) materials. Computation of elastic tensors and \(\Gamma\)-point phonon energies were performed using the ACENET\(^34\) cluster, taking advantage of the massive parallelization functionality of ABINIT.\(^36\) ABINIT composes wavefunctions as linear combinations of a plane wave basis set and performs calculations in reciprocal space.\(^37\)\(^,\)\(^38\)

Calculations of elastic tensors and phonon frequencies were performed using the response-function capability of ABINIT.\(^39\)\(^-\)\(^41\) Phonon frequencies were corrected for errors due to finite sampling on the effective charges by imposition of the acoustic sum rule (i.e., requiring that the frequencies of the acoustic branches are zero at \(\Gamma\)).\(^39\)

The CIF2Cell program\(^42\)\(^,\)\(^43\) was used to create input files from published crystal structure data.\(^5\)\(^,\)\(^44\)\(^,\)\(^45\) PBE GGA exchange–correlation functionals were used in all cases.\(^46\) In the cases of \(Al_2Mo_3O_{12}\) and \(Sc_2Mo_3O_{12}\), norm-conserving pseudopotentials generated using the OPIUM code\(^47\)\(^-\)\(^50\) from the Bennet and Rappe pseudopotential library\(^51\) were used. For \(ZrMgMo_3O_{12}\), two-projector optimized norm-conserving Vanderbilt pseudopotentials\(^52\) were used. These pseudopotentials were tested by comparison of calculated elastic moduli to experimental values for MgO (\(-7.2\%\) deviation),\(^53\) ZrO\(_2\) (\(-1.6\%\) deviation),\(^54\) and Mo (\(-3.4\%\) deviation)\(^4\)\(^-\)\(^5\) yielding reasonable results.\(^56\) The plane wave cut-off energy and \(k\)-point grid spacing were determined by convergence studies (Table 1); the criterion used was convergence of the internal pressure to within 1%. A \(k\)-point grid spacing smaller than 0.04 \(\text{Å}^{-1}\) was used in all cases. The structures were relaxed until the remaining pressure was less than 1 MPa. Changes in the unit cell axis lengths following relaxation are shown in Table 1.

The elastic and CTE tensors of \(Al_2Mo_3O_{12}\), \(ZrMgMo_3O_{12}\), and \(Sc_2Mo_3O_{12}\) (reported herein) and \(Y_2Mo_3O_{12}\) (from published studies)\(^16\) were used to create models of thermal stress in polycrystals of random texture, following a drop in temperature of 700 K, using the teFFT algorithm described in ref. 57. The teFFT algorithm simulates the elastic response to a change in temperature using a fast Fourier transform (FFT) approach to iteratively solve the constituent equations of thermoelasticity.\(^57\)\(^,\)\(^58\)

Since this method is only computationally limited by the speed of the FFT, simulations should scale with order \(n \log n\), where \(n\) is the number of nodes used in the model. Additionally, the spectral approach to solving the constituent equations of thermoelasticity only requires a structured rectilinear grid or image as an input, called the Fourier grid, forgoing the need for meshing.\(^57\) These aspects resulted in considerable computational time savings by comparison to finite-element methods, allowing much larger models to be studied. The microstructure models used were generated in DREAM.3D\(^59\) and consisted of 1190 randomly oriented, equiaxial grains on a 256\(^\)\(^3\) Fourier grid. A section of a modeled microstructure is shown in Fig. 1. Since the spectral approach requires periodic boundary conditions for the model, in the thermoelastic models polycrystalline structures were embedded in a compliant buffer layer. The buffer layer represents a region of infinite elastic compliance, which is created by

---

\(^1\) Mo was chosen rather than an oxide as the test material because MoO\(_2\) has a layered structure and therefore is an unsuitable point of comparison,\(^36\) and the bulk modulus of MoO\(_2\) has not been reported in the literature.
Al$_2$Mo$_3$O$_{12}$ showed elastic anisotropy similar to that of its thermal expansion, with only a small difference between the $b$- and $c$-axes. The overall elastic anisotropy of Al$_2$Mo$_3$O$_{12}$, expressed as the universal anisotropy parameter $A_U$, is equal to 1.9. By comparison, Y$_2$Mo$_3$O$_{12}$ has $A_U = 3.9$. Unlike in the case of Y$_2$Mo$_3$O$_{12}$, the axial Young’s moduli and directional compressibilities followed the expected trends and were inversely proportional to each other. The Voigt–Reuss–Hill (VRH) values for the bulk elastic constants of Al$_2$Mo$_3$O$_{12}$ were determined to be $K = 35.3$ GPa and $G = 36.2$ GPa. These stiffnesses are ca. double those determined experimentally for monoclinic Al$_2$Mo$_3$O$_{12}$ ($K = 13.5 \pm 1.3$ GPa, $G = 18.2 \pm 0.7$ GPa). A similar discrepancy was seen in the case of Y$_2$Mo$_3$O$_{12}$, obscuring whether the difference is due to temperature dependence of the elastic constants or the difference between the monoclinic and orthorhombic phases.

The calculated elastic stiffness tensor of orthorhombic ZrMgMo$_3$O$_{12}$ ($P2_1nb$ setting) is given by:

$$ c = \begin{bmatrix} 56.3 & 16.8 & 14.2 & 0 & 0 & 0 \\ 16.8 & 85.2 & 43.6 & 0 & 0 & 0 \\ 14.2 & 43.6 & 88.4 & 0 & 0 & 0 \\ 0 & 0 & 0 & 33.9 & 0 & 0 \\ 0 & 0 & 0 & 0 & 20.1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 18.0 \end{bmatrix} \text{GPa} \quad (3) $$

and the corresponding directional elastic moduli are shown in Table 3. The experimental thermal expansion tensor is shown for comparison of its anisotropy to that of c:

$$ a = \begin{bmatrix} 7.6 & 0 & 0 & 0 & 0 & 0 \\ 0 & 2.5 & 0 & 0 & 0 & 0 \\ 0 & 0 & -4.7 & 0 & 0 & 0 \end{bmatrix} \times 10^{-6} \text{K}^{-1} \quad (4) $$

As for Al$_2$Mo$_3$O$_{12}$, ZrMgMo$_3$O$_{12}$ shows increased stiffness along its thermomiotic axes both in terms of Young’s modulus and compressibility. The stiffnesses of the $b$- and $c$-axes were similar even though their CTEs are quite different in magnitude. The overall elastic anisotropy of ZrMgMo$_3$O$_{12}$ was very similar to that of Al$_2$Mo$_3$O$_{12}$; both have $A_U = 1.9$. The VRH bulk and shear moduli were 26.5 GPa and 23.8 GPa, respectively. These values are close to those obtained experimentally ($K = 31 \pm 3$ GPa, $G = 22 \pm 1$ GPa).

The calculated elastic stiffness tensor of orthorhombic Sc$_2$Mo$_3$O$_{12}$ ($Pbcn$ setting) is given by:

$$ c = \begin{bmatrix} 53.1 & 14.9 & 16.7 & 0 & 0 & 0 \\ 14.9 & 88.1 & 49.3 & 0 & 0 & 0 \\ 16.7 & 49.3 & 92.2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 31.8 & 0 & 0 \\ 0 & 0 & 0 & 0 & 15.8 & 0 \\ 0 & 0 & 0 & 0 & 0 & 18.5 \end{bmatrix} \text{GPa} \quad (5) $$

Fig. 1 A slice through the microstructure of a modeled polycrystal with randomly oriented grains. The relative orientations of the grains are shown as different colours, with similar colours corresponding to similar orientations. The compliant buffer layer is shown as a grey boundary.
and the corresponding directional elastic moduli are shown in Table 4. The experimental thermal expansion tensor\(^2\) is shown for comparison of its anisotropy to that of \(c\):

\[
\alpha = \begin{pmatrix}
11 & 0 & 0 \\
0 & -8.7 & 0 \\
0 & 0 & -8.4
\end{pmatrix} \times 10^{-6} \text{K}^{-1}. \tag{6}
\]

The elastic anisotropy of \(\text{Sc}_2\text{Mo}_3\text{O}_{12}\) \((A_U = 2.9)\) was larger than that of \(\text{Al}_2\text{Mo}_3\text{O}_{12}\) and \(\text{ZrMgMo}_3\text{O}_{12}\), which could be expected given its larger CTE anisotropy. The VRH values for the bulk and shear moduli were \(K = 24.0\) GPa and \(G = 22.3\) GPa; unlike in the cases of \(\text{Al}_2\text{Mo}_3\text{O}_{12}\) and \(\text{Y}_2\text{Mo}_3\text{O}_{12}\), the calculated bulk modulus of \(\text{Sc}_2\text{Mo}_3\text{O}_{12}\) is significantly less than the experimental value \((K = 32 \pm 2\) GPa from variable-pressure XRD)\(^{14}\).

Correlations of axial elastic properties with axial thermal expansion, axial Young's moduli \((Y_i)\), axial compressibilities \((\beta_i)\), and directional shear moduli \((G_{jk})\) are visualized in Fig. 2 as functions of the axial CTEs \((\alpha_i)\)\(^{1,5,6}\) for the three materials described above and \(\text{Y}_2\text{Mo}_3\text{O}_{12}\).\(^{1,6}\) The elastic behaviours of the thermomiotic \(b\)- and \(c\)-axes are correlated with their axial CTEs, while such a correlation is not seen for the \(a\)-axis. The \(b\)- and \(c\)-axes are stiffer than the \(a\)-axis except in the case of \(\text{Y}_2\text{Mo}_3\text{O}_{12}\), where the \(a\)-axis has a higher Young's modulus but also higher compressibility. Stiffer thermomiotic axes could decrease the bulk CTE of a polycrystal, as the increased stiffness would yield a larger contribution to the bulk expansion. As described below, this effect can be predicted in some cases. The trends in the VRH-averaged isotropic moduli (Fig. 2(d)) are more pronounced than those in the axial stiffnesses. A decrease in overall stiffness with increasingly negative thermal expansion can be seen clearly. When a thermomiotic material is used to counteract positive thermal expansion, its stiffness can be as important as its CTE in determining the amount of CTE reduction achieved,\(^{15,20,21,63}\) and therefore the negative correlation between stiffness and CTE might act to discourage the use of materials such as \(\text{Y}_2\text{Mo}_3\text{O}_{12}\) in applications. The trend relating the elastic moduli to the CTE is very similar to the previously reported correlation between the A site ionic force and the CTE,\(^5\) suggesting that polyhedral distortability is a common factor between thermal expansion and elastic properties in this group of materials.

The materials studied show significantly different behaviour when subjected to different stress conditions. The \(b\)- and \(c\)-axes

**Fig. 2** Calculated directional elastic properties of (a) Young's moduli, (b) compressibilities, and (c) shear moduli, as functions of axial thermal expansion along the \(a\)- (.), \(b\)- (A), and \(c\)- (.) axes for orthorhombic \(\text{Al}_2\text{Mo}_3\text{O}_{12}\), \(\text{ZrMgMo}_3\text{O}_{12}\), \(\text{Sc}_2\text{Mo}_3\text{O}_{12}\), and \(\text{Y}_2\text{Mo}_3\text{O}_{12}\) in the \(\text{Pbcn}\) or \(\text{P}_{21}\text{nb}\) setting. (d) Volumetric thermal expansion as a function of calculated VRH bulk and shear moduli for orthorhombic \(\text{Al}_2\text{Mo}_3\text{O}_{12}\), \(\text{ZrMgMo}_3\text{O}_{12}\), \(\text{Sc}_2\text{Mo}_3\text{O}_{12}\), and \(\text{Y}_2\text{Mo}_3\text{O}_{12}\). Axial CTEs and the elastic tensor of \(\text{Y}_2\text{Mo}_3\text{O}_{12}\) were taken from the literature; see the text for references.
show a decrease in uniaxial stiffness (Fig. 2(a)) with increasingly negative thermal expansion. However, when subjected to isotropic pressure (Fig. 2(b)), less variation in the stiffness is seen. These differences illustrate the importance of computational studies of the full elastic tensor, as only $\beta_{ii}$ can be obtained from experimental variable-pressure XRD measurements on polycrystalline samples. The directional shear moduli generally show increased stiffness for $G_{23}$ by comparison with $G_{13}$ and $G_{12}$, which is consistent with the increased stiffness of the $b$- and $c$-axes compared to the $a$-axis. This trend leads to the shear modulus in a plane ($G_{ij}$) increasing with the thermal expansion of the axis perpendicular to the plane ($\alpha_{ii}$).

The anisotropic Young’s moduli of $\text{Al}_2\text{Mo}_3\text{O}_{12}$, $\text{ZrMgMo}_3\text{O}_{12}$, $\text{Sc}_2\text{Mo}_3\text{O}_{12}$, and $\text{Y}_2\text{Mo}_3\text{O}_{12}$ are compared in all directions in Fig. 3. The overall trend of decreased overall stiffness with decreased CTE can be seen clearly, as can variations in the elastic anisotropy. In the case of $\text{Al}_2\text{Mo}_3\text{O}_{12}$, the predominant feature is the increased stiffness of the thermomiotic $bc$-plane relative to the $a$-axis. However, as the thermal expansion of the material becomes more negative, the stiffness of the $bc$-plane decreases more dramatically than that along the $a$-axis. Additionally, the stiffness within the $bc$-plane becomes more anisotropic, with the [011] and [011] directions becoming considerably stiffer than [010] and [001]. This results in the relatively large values of $G_{23}$ and discrepancies between $\alpha_{ii}$ and $\beta_{ij}$ seen in Fig. 2 and the indentations along [010] and [001] seen in Fig. 3.

**Phonon frequencies**

The $\Gamma$-point optic phonon frequencies calculated in ABINIT are presented in tabular form in the ESI, and visually in Fig. 4 (along with the previously reported phonon spectrum of $\text{Y}_2\text{Mo}_3\text{O}_{12}$). Fig. 4 shows the common features of the phonon spectra of the four materials studied: a band of low-energy librational, translational, and bending modes separated from stretching modes with higher energy, with asymmetric stretches at lower energies than symmetric stretches. As discussed in ref. 5, $\text{ZrMgMo}_3\text{O}_{12}$ has a larger spread of stretching mode energies due to the splitting of the A site into a Zr site and Mg site, but otherwise its $\Gamma$-point phonon spectrum is similar to that of the $\text{A}_2\text{Mo}_3\text{O}_{12}$ materials. The energies of the low-energy phonons can be compared more easily in Fig. 4, which shows the cumulative distribution function of the modes below 500 cm$^{-1}$. The phonons below ca. 200 cm$^{-1}$ are expected to have negative mode Grüneisen parameters and contribute to NTE, while those of higher energies are expected to have positive or near-zero Grüneisen parameters.

Fig. 4 shows that $\text{Y}_2\text{Mo}_3\text{O}_{12}$ has significantly more modes with energies below 200 cm$^{-1}$ and has generally lower phonon energies in this region, which is consistent with its observed NTE over a wide temperature range. Conversely, $\text{Al}_2\text{Mo}_3\text{O}_{12}$ has considerably fewer modes below 200 cm$^{-1}$, with a much broader distribution of its phonon frequencies in the region below 500 cm$^{-1}$. Of particular interest is a mode at 26 cm$^{-1}$ in $\text{Al}_2\text{Mo}_3\text{O}_{12}$ which is anomalously low in energy by comparison to the other translational and librational modes in this material. At some point in the Brillouin zone, this mode could be the soft mode with negative frequency that causes the orthorhombic–monoclinic phase transition. The mode distributions for $\text{Sc}_2\text{Mo}_3\text{O}_{12}$ and $\text{ZrMgMo}_3\text{O}_{12}$ are very similar, especially in the region below 200 cm$^{-1}$. $\text{Sc}_2\text{Mo}_3\text{O}_{12}$ has a negative CTE while $\text{ZrMgMo}_3\text{O}_{12}$ displays a zero thermal expansion, implying that the mode Grüneisen parameters of $\text{Sc}_2\text{Mo}_3\text{O}_{12}$ are more negative.
The calculated \( \Gamma \)-point phonon frequencies of Al\(_2\)Mo\(_3\)O\(_{12}\) and ZrMgMo\(_3\)O\(_{12}\) are compared to experimental Raman spectra (measured at room temperature) in the ESI.\(^\dagger\) Overall, the results of this comparison, in addition to the comparison of experimental elastic moduli to calculated values presented above, show that the calculated elastic and phononic properties of these materials, while not quantitatively accurate, show reasonable agreement with the experimental data.

**Axial Grüneisen parameters**

The axial coefficients of thermal expansion are determined by the anharmonicity of the interatomic potentials, as expressed through Grüneisen parameters, and by the stiffness tensor, which represents the resistance of the lattice to thermal deformation. The present computational analysis does not allow the axial Grüneisen parameters \( \gamma_{ii} \) to be determined directly, but using the calculated anisotropic elastic constants and phonon energies and the experimental CTE tensor the following expression can be invoked:\(^67\)

\[
\gamma_{ii} = \frac{V_m}{C_V} (c_{ii} \xi_{ii} + c_{ij} \xi_{ij} + c_{ik} \xi_{ik})
\]  

(7)

where \( V_m \) is the molar volume, \( C_V \) is the isochoric heat capacity, and \( c_{ij} \) and \( \xi_{ij} \) are stiffness and thermal expansion tensor elements, respectively. Here, \( C_V \) was calculated using the Einstein and Debye models following the procedure described in ref. 68 using the calculated elastic tensors and \( \Gamma \)-point phonon frequencies.\(^16\) The axial Grüneisen parameters were determined at \( T = 300 \) K for ZrMgMo\(_3\)O\(_{12}\), Sc\(_2\)Mo\(_3\)O\(_{12}\), and Y\(_2\)Mo\(_3\)O\(_{12}\),\(^9,16\) and at \( T = 550 \) K for Al\(_2\)Mo\(_3\)O\(_{12}\) (temperatures chosen so that the materials are in the orthorhombic phase). The results are shown in Fig. 5 and Table 5.

Thermal expansion along the \( b \)- and \( c \)-axes strongly correlates with the Grüneisen parameter along that axis, suggesting that vibrational modes with negative Grüneisen parameters along those axes are responsible for NTE. Essentially, this high degree of correlation is because the \( c_{ij} \xi_{ij} \) and \( c_{ik} \xi_{ik} \) terms in eqn (7) have opposite signs and nearly cancel. These terms are due to the Poisson effect, where a strain (in this case, thermally induced) along one axis causes a corresponding strain along the axes perpendicular to it.\(^69\) As shown in Tables 2–4, some of the axial Poisson ratios in these materials are quite large, close to the theoretical limit of 0.5 for stable isotropic materials.\(^70\) However, NTE along the \( b \)- and \( c \)-axes increases the CTE along
the $a$-axis due to the Poisson effect. The positive thermal expansion along the $a$-axis in Y$_2$Mo$_3$O$_{12}$ is caused entirely by this effect, as $\gamma_{aa}$ is negative. Similarly, the increase in thermal expansion along the $a$-axis in Sc$_2$Mo$_3$O$_{12}$ relative to ZrMgMo$_3$O$_{12}$ and Al$_2$Mo$_3$O$_{12}$ is due to its larger NTE along the $b$- and $c$-axes, as all three materials have similar values of $\gamma_{aa}$. Therefore, the Poisson effect is responsible for some of the thermal expansion anisotropy which causes microcracking in sintered bodies of Al$_2$Mo$_3$O$_{12}$ materials.\textsuperscript{19,20}

### Table 5: Axial Grüneisen parameters of orthorhombic Al$_2$Mo$_3$O$_{12}$, ZrMgMo$_3$O$_{12}$, Sc$_2$Mo$_3$O$_{12}$, and Y$_2$Mo$_3$O$_{12}$ in the Pbcn or P2$_1$nb setting

Thermal stress

Models of thermal stress due to thermal expansion anisotropy showed significant thermal stress in all four modeled materials. Thermal stress extrema reached hundreds of MPa, sufficient to cause significant microcracking, as seen experimentally in Al$_2$Mo$_3$O$_{12}$ and Al$_2$W$_3$O$_{12}$.\textsuperscript{19,20} The thermomiotic $b$- and $c$-axes are, on average, placed in tension while the $a$-axis is in compression due to thermal expansion mismatch. The net stress on the material is zero, as the boundaries are unconstrained. An example cross section of the thermal stress distribution in Y$_2$Mo$_3$O$_{12}$ can be seen in Fig. 6. The stress extrema are found at grain boundaries where several misaligned grains meet, and can be expected to cause intergranular microcracking.

The effect of elastic anisotropy on the thermal stress distributions can be quantified by comparison to Kreher’s model for elastically isotropic polycrystals.\textsuperscript{71,72} Anisotropic models have lower mean strain energy densities, $\langle W \rangle$, as shown in Table 6, indicating that elastic anisotropy acts to decrease thermal stress. In the elastically isotropic case, the average strain in the material is required to be equal to the thermal strain by the (unconstrained) boundary conditions and the conditions of static equilibrium.\textsuperscript{71,72} When the coupling of elastic anisotropy and thermal expansion anisotropy is included, the thermal expansion of the stiffer axes is slightly more expressed than that of the more compliant axes, which allows some relaxation of the thermal stress. This effect is seen in consolidated polycrystals as deviations from the intrinsic linear CTE (\(\Delta\alpha_i\)), shown in Table 6. While $\Delta\alpha_i$ is small in comparison to the bulk CTEs of Al$_2$Mo$_3$O$_{12}$ and Y$_2$Mo$_3$O$_{12}$, for ZrMgMo$_3$O$_{12}$ and Sc$_2$Mo$_3$O$_{12}$ the deviation is of similar magnitude to the intrinsic CTE. Therefore, elastic anisotropy could explain the relatively large differences observed in dilatometric results compared with the intrinsic CTE (e.g. from XRD) for these materials.\textsuperscript{2,5}

The stress distributions within the polycrystals were fit to statistical distributions as described in the ESI.\textsuperscript{†} The distributions in the different materials are generally similar, and using two lognormal distributions for the stress along each axis provides excellent fits to the data (see Fig. S4–S11, ESI\textsuperscript{†}). As the size of the A site cation increases from Al$^{3+}$ to Y$^{3+}$, increasing thermal expansion anisotropy is accompanied by decreasing stiffness (\textit{vide supra}). These two factors have opposite effects on the magnitude of the thermal stresses, resulting in similar stress distributions and extrema. This similarity indicates that it will prove difficult to use chemical control of the A site cation to reduce thermal stress due to thermal expansion anisotropy. When the thermal stresses are sufficiently large to cause microcracking, a further deviation from the intrinsic CTE can be found at elevated temperatures due to crack growth and healing.

### Table 6: Mean strain energy densities and deviations from the intrinsic linear CTE as predicted for the elastically isotropic case (where $\Delta\alpha_i = 0$) by Kreher’s method,\textsuperscript{71,72} and the present models

causing expansion and shrinkage, respectively, of the polycrystal-
line body.\textsuperscript{19,20}

In all cases, the two lognormal distributions in each fit had
opposite signs for their prefactors, leading to positive and
negative stress extrema each being fit by a single unbounded
lognormal tail. The utility of the lognormal distribution in fitting
the extreme stresses is likely connected to some underlying
physical phenomenon. The lognormal distribution is known to
arise as a result of multiplication of a series of random variables,
whereas the normal distribution arises from summation of a
series of random variables.\textsuperscript{73} Therefore, the lognormal fit to the
stress distribution implies some multiplicative character to their
origin. In anisotropic polycrystalline materials, thermal expansion
mismatches cause strains in the material, and consequently
reaction forces and stresses. In elastically isotropic materials,
the interactions of reaction forces throughout the material are
isotropic. This isotropy results in the stresses at any point being
related to the strains caused by thermal expansion anisotropy
throughout the remainder of material additively, and the normal
thermal stress distribution is a logical result. However, in a
material where the elastic constants are anisotropic, the transfer
of stresses through the material is not so simple. The elastic
anisotropy leads to the grains reacting differently to the applied
strains based on their orientations, with increased stress in
stiffer directions and \textit{vice versa}. Therefore, elastic anisotropy
introduces a multiplicative factor into the thermal stress dis-
tributions, since the relationship between the stress at a point
and the strain at another point is modified by the variations in
the stiffness tensor.

Conclusions

Materials in the $A_2M_3O_{12}$ and $AMgM_3O_{12}$ families were
shown to have significant elastic anisotropy, a finding consist-
tent with their characteristically large CTE anisotropy. The
thermomotic axes of these materials were shown to be stiffer
than the PTE axes, which could act to decrease their bulk CTEs.
However, the stiffness along the thermomotic axes decreases with
increasingly negative thermal expansion. The stiffness
along the PTE axes did not strongly correlate with their CTEs.
However, $Al_2M_3O_{12}$, $ZrMgMo_3O_{12}$, and $Sc_2Mo_3O_{12}$ were shown
to have similar axial Gr"uneisen parameters along their PTE axes,
with differences in thermal expansion being driven by
elastic factors. Calculated $\Gamma$-point optic phonon frequencies
showed differences between the materials in the low-energy
region which correlate with their thermal expansion behaviour,
and the optic phonon data compared to experimental Raman
spectra validated the results.

The thermal stress distributions calculated herein show that
thermal expansion anisotropy can cause large thermal stresses in
$A_2M_3O_{12}$ materials, enough to cause significant microcracking
upon heating and cooling. The distributions of the thermal
stresses are affected by the properties of the CTE and elastic
tensors. The results indicate that the stress distributions in the
four members of the $A_2M_3O_{12}$ family studied are quite similar.

In both cases, maximum tensile and compressive thermal
stresses on the order of 0.5 GPa can be expected, with positive
and negative extrema being well-described by lognormal distri-
butions. The elastic tensors were found to couple with the
thermal expansion tensors to produce small deviations in the
bulk CTE, which were large by comparison to the intrinsic CTE
in the cases of $ZrMgMo_3O_{12}$ and $Sc_2Mo_3O_{12}$.
