The photochemistry of mono- and dinuclear cyclometalated bis(tridentate)ruthenium(II) complexes: dual excited state deactivation and dual emission†

Christoph Kreitnera,b and Katja Heinzea,*

The synthesis and characterization of a series of weakly emissive mononuclear cyclometalated [Ru(dpb-R)(tpy)] complexes with functional groups R of varying electron-donating characters at the dpb ligand are described (dpbH = 1,3-di(2-pyridyl)benzene, tpy = 2,2′,6′,2″-terpyridine, 1+: R = NHCOMe, 2+: R = NH2, 3+: R = COOEt, 4+: R = COOH). Steady-state emission spectroscopy in the temperature range between 298 K and 77 K revealed a previously unrecognized excited state deactivation pathway via low-lying triplet ligand-to-ligand (3LLCT) charge transfer states in addition to the well-known pathway via 3MC states. Thermal activation barriers for depopulation of the emissive metal-to-ligand charge transfer (3MLCT) states via the 3MC (metal-centered) and 3LLCT states were determined experimentally for complexes 1+, 2+ and 3+. The experimental results were further corroborated by calculating the respective 3MLCT–3LLCT and 3MLCT–3MC transition states and their energies with density functional theoretical methods. The R substituent modifies the energy difference between the 3MLCT and 3LLCT states and the corresponding activation barrier but leaves the analogous 3MLCT/3MC energetics essentially untouched. Additionally, the dinuclear complex ([tpy]Ru(dpb-NHCO-dpb)Ru(tpy)]2+, 6†, containing a biscyclometalating bridge was devised. Despite the asymmetric nature induced by the amide bridge, the mixed-valent cation 6† is ascribed to Robin–Day class II with a broad and intense intervalence charge-transfer (IVCT) absorption (λmax = 1165 nm). Upon optical excitation, the RuII/RuII complex 6† exhibits dual emission in liquid solution from two independently emitting 3MLCT states localized at the two remote [Ru(tpy)] fragments. No equilibration via Dexter energy transfer is possible due to their large distance and short excited state lifetimes.

Introduction

Polypyridine complexes of ruthenium(II) have been known and studied for the past sixty years.1,2 Although the fundamentals of their photo- and electrochemical properties are well understood,3–7 research efforts have not diminished over the last few years mainly due to a widespread potential for applications for this class of metal complexes. These vary from photoredox catalysis,8–12 over light sensitization in dye-sensitized solar cells,13 and sensing applications in biological14,15 and chemical16 contexts to optoelectronics.17

The prototype of this class of complexes is [Ru(bpy)]3+(bpy = 2,2′-bipyridine), whose photophysical properties have been extensively studied and are well understood. Under visible light irradiation, excitation into a singlet metal-to-ligand charge transfer (1MLCT) state occurs (λmax = 452 nm, εmax = 14.6 M−1 cm−1).1,3 This state undergoes rapid and quantitative intersystem crossing onto the triplet hypersurface18,19 populating a long-lived 3MLCT state that is phosphorescent at room temperature (τem = 621 nm, φ = 0.095, τ = 855 ns in MeCN).20,21 Upon cooling, both, emission quantum yield and excited state lifetime, increase drastically. Using lifetime measurements at varying temperatures, T. J. Meyer and coworkers showed that this temperature dependence is due to a thermally accessible d–d excited state (metal centered, 3MC) that rapidly undergoes vibrational relaxation into the ground state (1GS).20,22 Additionally, this excited state is dissociative in nature and enables [Ru(bpy)]3+ to undergo photosubstitution reactions.20,22,23
To suppress these reactions and also to circumvent the chiral nature of \([\text{Ru(bpy)}_3]^{2+}\) stronger chelating, tridentate ligands such as tpy (tpy = 2,2′:6,2′-terpyridine) were introduced in bis(tridentate)ruthenium(II) complexes.\(^5\) Their meridional coordination geometry\(^2\) allows the functionalization of the ligand periphery without resulting in stereoisomers. A major drawback of these complexes compared to their bpy counterparts is the almost complete lack of emission at room temperature (\(\phi = \frac{1}{2\pi} \times 10^{-6}\)).\(^5,\)\(^6\)\(^2\) Due to the weaker ligand field caused by the smaller bite angle of the terpyridine ligand (N–Ru–N \(\approx 79°\)), the emissive \(^3\)MLCT states of \([\text{Ru(tpy)}_2]^{2+}\) are very efficiently depopulated \(\pi\) low-lying \(^3\)MC states.\(^5\) Upon cooling, thermal depopulation of the emissive state is retarded yielding bright luminescence at 77 K (\(\lambda_{\text{em}} = 599 \text{ nm}, \phi = 0.48, \tau = 110 \mu\text{s in MeOH/EOH}\)).\(^2\)

Various attempts have been made to regain room temperature luminescence from bis(tridentate)ruthenium(II) complexes. By introducing an electron-donating functional group on one of the terpyridine ligands, the energy of the \(^3\)MC state is increased with respect to the \(^3\)MLCT state energy rather selectively.\(^5\) Similarly, electron-accepting functionalities lower the \(^3\)MLCT state energy.\(^5\) Combining these two approaches in a push–pull system, the activation barrier for depopulation of the emissive \(^3\)MLCT state is increased. As a result, room temperature quantum yields of up to 0.003 and excited state lifetimes of 50 ns are achieved.\(^5,\)\(^2\)\(^8\)–\(^3\)\(^1\) Since the coordination mode of the tpy ligand with five-membered chelate rings only allows for rather constrained geometries around the metal center with small bite angles, several research groups focussed on expanding the ligand backbone to increase the overlap between the ruthenium d orbitals of the \(e_g\) set and the nitrogen lone pairs. This yields an enlarged ligand field splitting and thus makes \(^3\)MC states as deactivation pathway thermally less accessible at room temperature.\(^3\)\(^2\)\(^–\)\(^3\)\(^5\) Following this concept, bis(tridentate)ruthenium(II) complexes were synthesized with optical properties comparable to those of \([\text{Ru(bpy)}_3]^{2+}\) (\(\phi = 0.30, \tau = 3.3 \mu\text{s}\)).\(^3\)\(^3\)

In a very similar approach, by introduction of very strong \(\sigma\)-donors in the coordination sphere, the ligand field splitting can be increased compared to \([\text{Ru(tpy)}_2]^{2+}\). Conceptually, this was shown by Berlinguette and Schubert using N-heterocyclic carbene containing tridentate ligands (C'N'C coordination mode) with quantum yields of 0.11 and excited state lifetimes of up to 8 \(\mu\text{s}\).\(^3\)\(^6\) Disappointingly, attempts using 1,3-di(2-pyridyl)benzene (dpbH), deprotonated in the 2-position of the central benzene ring, as a strong cyclometalating \(\sigma\)-donor ligand in conjunction with tpy as a \(\pi\)-accepting ligand \([\text{Ru(dpb)}(\text{tpy})]\), gave only very weakly emissive complexes.\(^3\)\(^0\)\(^–\)\(^3\)\(^7\)\(^–\)\(^3\)\(^0\) This was originally ascribed to a very small activation barrier for thermal depopulation of the emissive \(^3\)MLCT state \(\pi\) low-lying \(^3\)MC states since the cyclometalation at the central position of the dpb ligand merely shifts one of the \(^3\)MC states to a higher energy.\(^3\)\(^0\) Recently, we have suggested that the introduction of a very strong push–pull arrangement across the metal center additionally gives rise to low-lying triplet ligand-to-ligand charge transfer \(^3\)LL(CT) states.\(^4\)\(^0\) Since the involved ligands are orthogonal to one another in the meridional coordination geometry, so are the spin-carrying orbitals. Hence, emission from such \(^3\)LL(CT) states is symmetry-forbidden and leads to efficient radiationless deactivation of the excited state.

To further study this phenomenon and to elaborate a general view, the work presented herein devised four cyclometalated ruthenium complexes \([\text{Ru(dpdb-R)(tpy)}]\) with varying substituents at the 5-position of the dpb ligand (R = NHCOME, \(^1\)R; R = NH2, \(^2\)R; R = COOEt, \(^3\)R; R = COOH, \(^4\)R). Using these, it is possible to systematically study the impact of varying push–pull strengths across the metal center on the ground and excited state properties of these cyclometalated complexes. By employing steady-state emission spectroscopy, we demonstrate that the occurrence of low-energy \(^3\)LL(CT) states is a common theme in cyclometalated bis(tridentate)ruthenium complexes providing a second excited state deactivation pathway in addition to the well-known pathway mediated by \(^3\)MC states.

Additionally, the presence of free amino and carboxylic acid groups allows the straightforward formation of a dinuclear complex with an amide-linked biscyclometalating bridging ligand \[\Pi(\text{tpy})\text{Ru(dpdb-NHCO-dpb)}\Pi(\text{tpy})\] that we synthesized and studied as well. Dinuclear bisruthenium complexes received wide interest since the discovery of the mixed-valent Creutz-Taube ion, \([\text{NH}_3]_2\text{Ru(µ-pz)}\text{Ru(NH}_3)_2]^{2+} (\text{pz} = \text{pyrazine})\).\(^4\)\(^1\)–\(^4\)\(^3\) The ruthenium oxidation states within this mixed-valent complex cannot be assigned unambiguously. Depending on the spectroscopic method either 2+/3+ or 2.5+/2.5+ is obtained.\(^4\)\(^4\)–\(^4\)\(^7\) Dinuclear mixed-valent complexes are assigned to three different groups based on Robin’s and Day’s classification.\(^4\)\(^8\) Systems with entirely localized valences and no electronic coupling between the redox centers in the mixed-valent state are referred to as Robin–Day class I, and systems with entirely delocalized valences are assigned as class III. Class II describes valence-localized complexes with measurable electronic interactions between the redox sites. The theoretical basis for an accurate physicochemical treatment of Robin–Day class II complexes was laid by Hush\(^4\)\(^9\)–\(^5\)\(^1\) describing the photochemical electron transfer occurring between the donor and acceptor sites \([\text{M}^{n+} - \text{M}^{(n+1)}] \rightarrow \text{M}^{(n+1)-} - \text{M}^{n+}\). This process yields an intervalence charge transfer (IVCT) absorption that is typically observed in the Near Infrared (NIR) region of the electronic absorption spectrum of a Robin–Day class II compound. According to Marcus–Hush theory, this IVCT band is correlated with the electronic coupling parameter \(V_{\text{ab}}\) between the redox centers calculated as: \(V_{\text{ab}} = 2.06 \times 10^{-12} \nu_{\text{max}}\epsilon_{\text{max}}\nu_{\text{L/2}}^{1/2}\rho^2\) with the absorption maximum \(\nu_{\text{max}}\) in \(\text{cm}^{-1}\), the extinction coefficient \(\epsilon_{\text{max}}\) at \(\nu_{\text{max}}\) in \(\text{M}^{-1}\text{cm}^{-1}\), the full width at half maximum \(\nu_{\text{L/2}}\) in \(\text{cm}^{-1}\) and the donor-acceptor distance \(r\) in Å.\(^4\)\(^7\)\(^\)\(^5\)\(^2\)

Several amide-bridged dinuclear bis(terpyridine)ruthenium(II) complexes and their mixed-valent counterparts have been described in the literature.\(^5\)\(^3\)–\(^5\)\(^5\) While the back-to-back linked \((n = 0)\) or phenylene-extended \((n = 1–2)\) dinuclear bis(terpyridine)ruthenium(II) complexes \([\Pi(\text{tpy})_2\text{Ru(tpy}_1\text{,4-C}_4\text{H}_4\text{,tpy})\Pi(\text{tpy})]\) \((\text{tpy} = \text{4-tolyterpyridine}, 1,4-C_4\text{H}_4 = \text{para-phenylene})\)
exhibit electronic coupling of the metal centers in the mixed-valent state to a small extent \( n = 0; V_{ab} = 0.047 \text{ eV}, n = 1; V_{ab} = 0.030 \text{ eV}, n = 2; V_{ab} = 0.022 \text{ eV} \) \(^{56,57}\) the introduction of an amide bridge seems to reduce the molecular and redox-chemical symmetry enough to prevent the electronic interactions entirely.\(^{54,55}\) In the cyclometalated analogue of the dinuclear back-to-back linked bis(terpyridine)ruthenium complex, \( \{[tppy \text{Ru}(dpb-dpb)](tpy)^{2+} \} \), on the other hand, the metal–metal interaction is increased to \( V_{ab} = 0.127 \text{ eV} \) \(^{58,59}\) This increase was attributed to an energy shift of the bridge’s frontier orbitals to better match those of the metal centers.\(^{59,60}\) In this work, we study to what extent the insertion of an NHCO group into the bridge reduces the electronic coupling between the metal centers in the mixed-valent state \( 6^{3+} \) and the interaction of the triplet excited states of \( 6^{2+} \).

**Results and discussion**

**Synthesis and characterization of mono- and dinuclear complexes**

The synthesis (Scheme 1) of the target mononuclear complexes was carried out following a previously described synthetic route starting from \( \text{RuCl}_3(\text{tpy}) \).\(^{40,58}\) In the first step, this precursor is activated by chloride abstraction using silver tetrafluoroborate. The resulting solvent complex intermediate was subsequently treated with the respective dipyridylbenzene ligand \( \text{L1 or L2}^{40} \) to give the amide or ester substituted \( \{[\text{Ru}(\text{dpb-R})(\text{tpy})]\}^{+} \) complexes \( 1(\text{PF}_6) \) and \( 3(\text{PF}_6) \) in good yields. Cleavage of the functional groups for the liberation of free amine or carboxylic acid was achieved in aqueous methanolic solutions using sodium hydroxide as a base and hydrazine as a reductant to prevent oxidative decomposition. This hydrolysis protocol gives comparable yields to the hydrolysis of structurally related ruthenium complexes by trimethylamine employed by Berlinguette and coworkers.\(^{61}\)

In order to accomplish the coupling reaction between the free acid and the amine moieties of \( 2^{2+} \) and \( 4^{2+} \) to the dinuclear complex \( 6^{2+} \), activation of the acid component is necessary. This was achieved similarly to a previously employed technique using \( \text{N-hydroxybenzotriazole (HOBt)} \) and \( \text{N,N\text{-dii}-propylocarboxidiimide (DIC)} \)\(^{55,62}\) Compared to the amide coupling reaction between bis(terpyridine)ruthenium(II) amino acid derivatives described previously,\(^{54,55}\) the coupling had to be performed at elevated temperatures, possibly attributed to the reduced acidity of the amino functionality and relatively weak nucleophilicity of the OBt ester compared to other active esters.

All complexes were characterized using 1D- and 2D-NMR techniques (ESI, Fig. S1–S14†) as well as ESI and high-resolution ESI mass spectrometry (ESI, Fig. S15†). The purity of all compounds under study was confirmed by elemental analyses. Successful amide cleavage (\( 1(\text{PF}_6) \rightarrow 2(\text{PF}_6) \)) is proven by the disappearance of the NH \( (8.62 \text{ ppm}) \) and CH\(_3\) \( (2.23 \text{ ppm}) \) resonances in the proton NMR spectrum of \( 2(\text{PF}_6) \). Simultaneously, a new significantly broadened resonance appears at \( 4.24 \text{ ppm} \) indicating the presence of a free amino group. Similarly, ester saponification (\( 3(\text{PF}_6) \rightarrow 4(\text{PF}_6) \)) yields a loss of the characteristic CH\(_2\) and CH\(_3\) proton resonances of the ethyl group while essentially leaving the aromatic region of the \( ^1\text{H} \) NMR spectrum unaffected. For the hydroxybenzotriazole ester \( 5(\text{PF}_6) \), the resonances of the dipyridylbenzene ligand, predominantly those in the 2B-position, are shifted to a lower field. This is in agreement with the formation of a more electron-deficient species that is activated towards nucleophilic attack.

---

\( \text{Scheme 1} \) Synthesis of the mononuclear complexes \( 1(\text{PF}_6) \)–\( 5(\text{PF}_6) \) and the dinuclear complex \( 6(\text{PF}_6)_2 \) from \( \text{RuCl}_3(\text{tpy}) \). Atom numbering for NMR assignment is included.
Interestingly, the functional group attached to the dpb ligand strongly affects the $^{13}$C chemical shift of the coordinating carbon atom. While this resonance is found at 239.5 ppm in complex $5(PF_6)$ with the strongly electron-withdrawing COOH substituent, it is shifted upfield to 233 ppm in complexes $3(PF_6)$ and $4(PF_6)$ with COOEt and COOH functional groups. In the N-substituted complexes, it is found at even lower chemical shifts, namely at 217.2 ppm for $1(PF_6)$ and at 208.9 ppm for $2(PF_6)$. This also reflects the electrochemistry at the ruthenium center (vide infra).

Evidence for the success of the amide coupling between $2(PF_6)$ and $5(PF_6)$ is gained from the $^1H$ NMR spectrum of $6(PF_6)$. The proton resonance at low field (9.63 ppm) with an integral of a single proton indicates the presence of an amide bridge. Additionally, all aromatic signal sets occur four times in a 1:1:1:1 ratio. Although the resonances of the two terpyridine ligands are distinguishable due to the different substituents at the remote dpb ligands, an unambiguous assignment to one of the two capping ligands is impossible. The ESI mass spectrum, which shows the required peaks at $m/z = 586.6$ for $6^{2+}$ and at 1318.3 for $6(PF_6)^+$ with isotope patterns characteristic for a complex containing two ruthenium atoms, gives additional support to the successful formation of the dinuclear complex.

IR spectroscopy further confirms all structures under study (ESI, Fig. S16†). All the complexes exhibit an intense IR absorption at 843 cm$^{-1}$ arising from F–F stretching vibrations within the PF$_6^-$ counterion. The amino-substituted complex $2^+$ shows a broad, intense absorption at 3420 cm$^{-1}$ arising from N–H stretching vibrations of the NH$_2$ group. The amide containing complexes $1^+$ and $6^{2+}$ exhibit a broad absorption band at around 3220–3230 cm$^{-1}$ ascribed to the N–H stretch along with intense C=O vibrations at 1650 cm$^{-1}$ and 1635 cm$^{-1}$, respectively. Similar C=O vibrations are observed for the carboxy-substituted complexes $3^+$ and $4^+$, with that of the ester occurring at 1695 cm$^{-1}$ and that of the carboxylic acid at 1665 cm$^{-1}$. Additionally, the carboxylic acid $4^+$ exhibits a broad absorption at 3440 cm$^{-1}$ (O–H stretch) along with absorptions in the range between 3000 and 2300 cm$^{-1}$ typical for carboxylic acids.

**Electrochemical properties of complexes $1(PF_6)$–$4(PF_6)$ and $6(PF_6)_2$**

The cyclic voltammograms of the complexes $1(PF_6)$–$4(PF_6)$ and $6(PF_6)_2$ are depicted in Fig. 1 and the respective electrochemical data are summarized in Table 1. For all mononuclear complexes, $1(PF_6)$–$4(PF_6)$, a single reversible oxidation is observed in the range between –0.2 V and 0.28 V versus the ferrocene/ferrocenium redox couple. It is ascribed to the Ru$^{II}$/Ru$^{III}$ couple. The electrochemical data of the ethyl ester-substituted complex $3(PF_6)$ agree well with those of the methyl ester reported in the literature. With increasing electron-accepting properties of the respective substituent, this redox process is shifted to higher potentials by almost 500 mV. This suggests a strong contribution of the dpb ligand to the highest occupied molecular orbital (HOMO) of these complexes.

Density functional theory (DFT) calculations further illustrate and enlighten these experimental findings. We have shown previously that the B3LYP functional along with a split-valence double-$\tilde{\zeta}$ basis set and polarization functions on all non-hydrogen atoms (def2-SV(P)) provides reasonable access to the electronic properties of the numerous charge transfer states of the complexes under study when combined with the ZORA relativistic approximation and a continuum solvent model (COSMO).

Indeed, DFT calculations for the singlet ground states of the respective cationic complexes nicely reproduce the dependence of the energy of the HOMO from the substitution pattern (Fig. 2). Additionally, the shape of the HOMO parallels that of the doublet spin density of the Ru$^{III}$ complexes $1^{2+}$–$4^{2+}$ (ESI, Table S2†) supporting the fact that oxidation occurs on both the metal site and the dpb ligand. At substantially higher potentials, a second, irreversible oxidation is observed. It is again assigned to a mixed metal/dpb ligand oxidation yielding a [Ru(dpb)]$^{3+}$ state as suggested previously by DFT calculations for analogous complexes. The dependence of this second oxidation from the substitution pattern is even more pronounced so that its potential ranges from 0.35 V for amine-substituted $2(PF_6)$ to 1.49 V for ester-substituted $3(PF_6)$.

All four mononuclear complexes exhibit one reversible and several unresolved irreversible reductions. According to DFT calculations on the ground and the one-electron reduced states of $1^-$–$4^-$ ($1^0$–$4^0$), the first reduction is ascribed to a
tpy-centered reduction (ESI, Table S2†). The COOH-substituted complex 4(PF6) shows a stripping peak upon reoxidation following the first reduction. We ascribe this phenomenon to precipitation of the neutral complex moiety [RuII(dpb−COOH)(tpy)]4+ on the electrode surface and subsequent redissolution after reoxidation to 4+.55

Due to the orthogonal mer-coordination of the two tridentate ligands, the electronic influence of the different functional groups attached to the dpb ligand on the tpy ligand is reduced to a minor inductive effect. Consequently, the first reduction occurs at very similar potentials for all four complexes in the range between −1.86 (COOH-substituted 4(PF6)) and −1.95 V (NH2-substituted 2(PF6)) spanning just 90 mV. Accordingly, the HOMO–LUMO gap, which is closely correlated to the difference of the redox potentials of the first reduction and oxidation, varies considerably in the order 4+ ≈ 3+ > 1+ > 2+ (Table 1). This trend is in excellent agreement with DFT calculations (Fig. 2 and Table 1).

Table 1 Electrochemical data of complexes 1(PF6)–4(PF6) and 6(PF6)2, obtained from 0.1 mol l−1 [nBu4N][PF6] containing acetonitrile solution. Potentials are referenced against the FcH/FcH+ couple. Energy differences E_HOMO – E_LUMO are obtained from DFT calculations (see the MO diagram in Fig. 2).

Fig. 2 Molecular orbital energy diagram of complexes 1(PF6)–4(PF6) and 6(PF6)2 obtained from DFT calculations (B3LYP, def2-SV(P), COSMO (acetonitrile), ZORA). Frontier orbitals are depicted exemplary for 3(PF6) since the shape of the respective orbital varies only marginally among the mononuclear complexes (see also ESI, Table S1†). Hydrogen atoms are omitted for clarity.
All complexes exhibit follow-up oxidation peaks in the range between −1 and −0.5 V once reduction has been carried out beyond −2 V. We had observed such behaviour previously both in mono- and dinuclear bis(terpyridine)ruthenium(n) complexes and cyclometalated ruthenium complexes bearing amide functionalities. We had suggested that these follow-up oxidations are associated with species that are formed after reduction of the substantially acidified amide NH proton (hydrogen formation).\(^5\) The observation of similar processes in complexes such as \(3\)(PF\(_6\)) and \(4\)(PF\(_6\)) lacking NH functionalities contradicts this hypothesis. In fact, such more or less pronounced follow-up reoxidation peaks can be found for a large variety of tpy containing complexes of different metals such as chromium,\(^6\) manganese,\(^7\) and ruthenium,\(^3\) once a sufficient number of reduction events have taken place at the tpy unit. The triplet spin densities of the twofold reduced complexes \(1^{−}−4^{−}\) do not provide further hints on possible follow-up reactions (ESI, Table S2†). Compared to the respective \(1^{+}\)GS structures, their geometries are undistorted with a spin density homogeneously distributed over all three pyridine rings of the terpyridine ligand.

For the dinuclear complex \(6\)(PF\(_6\))\(_2\), cyclovoltammetric studies reveal a single reversible two-electron reduction, as evidenced from square-wave voltammetry, followed by an intense stripping peak. Again, this stripping peak arises from precipitation of the large uncharged complex \(6^{0}\) on the electrode surface and redissolution after reoxidation to \(6^{2+}\). The first, unsplitted reduction processes are ascribed to tpy-centered reductions occurring at both terminal ligands of the bimetallic complex as evidenced from DFT calculated triplet spin densities of \(6^{0}\) (ESI, Table S3 and Fig. S17†). Additionally, two reversible oxidation processes at 0.05 and 0.29 V, respectively, are observed. Based on the redox potentials of the mononuclear complexes, these can be ascribed to a primary oxidation of the NH-substituted complex fragment followed by oxidation of the CO-substituted moiety. Interestingly, the difference of the two oxidation potentials is slightly increased by 20 mV compared to that of the mononuclear complexes \(1^{+}\) and \(3^{+}\) (240 versus 220 mV, Table 1). This might be due to spatial charge accumulation or to a weak electronic communication between the two complex fragments in the mixed-valent state \(6^{2+}\). Missing shifts of the electrochemical potentials of asymmetric dinuclear complexes compared to similar mononuclear complexes or negligible splittings between the \(\text{Ru}^{II}\text{Ru}^{II}/\text{Ru}^{III}\text{Ru}^{II}\) and the \(\text{Ru}^{II}\text{Ru}^{III}/\text{Ru}^{II}\text{Ru}^{III}\) oxidation potentials in symmetrical complexes have already been observed with other bimetallic bis(tridentate)ruthenium complexes.\(^5\)−\(^7\) Some of these complexes were accompanied by a weak electronic interaction between the Ru centers while others showed no metal–metal interaction. These examples illustrate that a clear conclusion as to whether electronic communication occurs between the metal centers of the complex fragments is impossible purely based on these electrochemical data.\(^7\)

UV-Vis spectroscopic properties of complexes \(1\)(PF\(_6\))−\(4\)(PF\(_6\)) and \(6\)(PF\(_6\))

The absorption spectra of all mononuclear complexes (Fig. 3) exhibit very similar features. Besides intense transitions in the UV region attributed to π−π* transitions within the ligands, four discernible absorption bands are observed in the visible range between 350 and 650 nm. DFT calculations\(^10\)\(^,\)\(^3\) and resonance Raman spectroscopy studies\(^10\) suggest that such bands characteristic for cyclometalated ruthenium complexes containing polypyridine and N^C, N^C^N or N^N^C ligands arise from metal-to-ligand charge transfer transitions (MLCT) involving both the polypyridine and the cyclometalating ligand as electron accepting sites.

As the visible-range absorption bands are governed by MLCT transitions involving both ligands, variation of the functional group on the cyclometalating ligand greatly affects the position of the low-energy absorption maximum (Table 2). While the ester- or acid-substituted complexes \(3^{+}\) and \(4^{+}\) exhibit absorption maxima at 493 nm, the respective maximum of amide-substituted \(1^{+}\) is observed at 509 nm and that of the amine complex \(2^{+}\) is found at 550 nm (Fig. 3). This trend is in good agreement with the HOMO–LUMO gap (Table 1 and Fig. 2) in this series of complexes. In contrast, DFT calculations reveal that the most intense Ru → tpy MLCT transitions (HOMO−1 (d_{zx}) → LUMO) are not responsible for the observed trend since they appear at very similar energies for all four complexes (transition 5 in ESI, Tables S4–S7†). This is easily understood based on a closer examination of the orbitals of the complexes \(1^{−}−4^{−}\) involved in this transition (Fig. 2 and ESI, Table S1†): the symmetry of the LUMO (tpy) only allows for constructive interference with the d_{zx} orbital of the
metal (HOMO-1). On the other hand, both, HOMO-1 and LUMO are perpendicular to the Ru δz orbital and the dpb π-orbital which strongly contribute to the HOMO. Hence, the dpb functional group’s impact on the involved orbitals is again reduced to a minor inductive effect explaining the weak dependence of the Ru → tpy MLCT transitions on the dpb substituent.

The strong bathochromic shift of the experimental absorption maximum accompanying the more electron-donating N-acetyl amino and amino substituents at the dpb ligand in fact arises from symmetry-allowed δz(Ru) → dpb MLCT transitions. Especially the HOMO → LUMO+2 transition plays a key role within the absorption characteristics (transition 6 in Tables S4–S7†). These transitions are calculated at 486 (1°), 507 (2°), and 456 nm (3° and 4°), respectively, and they nicely reproduce the trends within the absorption maxima of the respective complexes (Table 2). This fully confirms that the two main 1MLCT transitions in the visible range of the electronic spectrum, namely δz(Ru) → tpy and δz(Ru) → dpb, are electronically decoupled for simple symmetry reasons.

At first sight, the absorption spectrum of the dinuclear complex 6+ resembles the absorption spectra of the carboxyl-substituted mononuclear complexes 3° and 4° with roughly doubled extinction coefficients due to its dinuclear nature (Fig. 3). A closer inspection reveals that the spectrum of the dinuclear complex is much better reproduced by a 1 : 1 superposition of the absorption spectra of the ester- and the amide-linked dinuclear ruthenium(II) complexes with tridentate ligands. Since in this study the visible absorption-spectroscopic fingerprints of the two subunits are more distinct than in the literature-known bimetallic examples, the superimposed nature of the absorption bands of 6+ is more obvious. In principle, the two [Ru(dpb)(tpy)]1 subunits are essentially uncoupled in the Ru²Ru² state.

Table 2  Experimental UV-Vis absorption and emission data of the mononuclear complexes 1(PF₆), 2(PF₆), 3(PF₆), and 4(PF₆) as well as the dinuclear complex 6(PF₆)₂. Absorption and emission data are obtained from (deaerated) acetonitrile solution, and low-temperature emission data are recorded in butyronitrile. Excitation wavelengths are given in parentheses where wavelength dependence of the emission maximum was observed, otherwise λₐₑₓ = 500 nm

Fig. 4 Visible range of the absorption spectra of 1° (blue), 3° (red) and 6° (green) in dry acetonitrile solution as well as superposition (1° + 3°) (black, dashed line) and difference spectra (3° – 1°) (black, solid line).

To probe the metal–metal interaction in the mixed-valent state 6+, careful in situ chemical oxidation of 6(PF₆)₂ in acetonitrile solution was carried out using [NH₄]₂[Ce(NO₃)₆] as an oxidant (E ≈ 0.8–0.9 V)72. Its oxidation potential is high enough to allow for a stepwise double oxidation of 6+ to the bis(ruthenium(III)) complex 63+. Absorption spectra (Fig. 5) were recorded each time after addition of 0.25 equivalents of the oxidant. A broad, symmetrical absorption band appears in the near infrared (NIR) region of the absorption spectrum upon addition of 0 → 1 equivalents of the oxidant with an absorption maximum at 1165 nm (8585 cm⁻¹, εmax ≈ 2620 M⁻¹ cm⁻¹, full width at half maximum Δν₁/₂ = 600 cm⁻¹). Simultaneously, a second, significantly sharper band appears in the red region (maximum at 716 nm). A set of isosbestic points is observed at 273, 325, 335, 486, and 619 nm indicating a clean reaction without side products. Upon addition of more oxidant (1 → 1.5 eq.), a new set of isosbestic points is observed at 273, 325, 335, 486, and 810 nm. Hence, the reaction 6+ → 63+ → 64+ occurs stepwise as expected from the separation of the first and second oxidation waves in the cyclic voltammogram of 6+.

Simultaneously, the intensity of the NIR band decreases while the band in the red region rises further. Interestingly, upon addition of more oxidant (1.5 → 2 eq.), the isosbestic points are lost and a new absorption band appears at around 940 nm (ESI, Fig. S18†).
nuclear complexes (from DFT calculation) was taken into account despite the fact RuII(dpb-NHCO-dpb)RuIII(tpy)]3+ and [(tpy)RuIII(dpb-NHCO-dpb)RuII(tpy)]3+ in the same conditions (ESI, Fig. S19).

The absorption band in the red spectral region on the other hand is ascribed to ligand-to-metal (LMCT) transitions in the newly formed RuIII fragment. The absorption band at 716 nm and 1165 nm (Fig. 5) are recorded after addition of 0.25 equivalents each time.

Table S9

Although a straight-forward Hush analysis of the band shape and energy of the IVCT band is formally not correct due to the energy difference \( \Delta G_0 \) of the two valence isomers \([\text{tpy}]\text{Ru}^{III}(\text{dpb-NHCO-dpb})\text{Ru}^{III}(\text{tpy})\] and \([\text{tpy}]\text{Ru}^{III}(\text{dpb-NHCO-dpb})\text{Ru}^{II}(\text{tpy})\], the latter being the lower energy isomer, we predict such a symmetry allowed IVCT transition (d→π* transition) in the bridged dinuclear ruthenium complex \([\text{EtOOC-tpy}]\text{Ru}^{II}(\text{tpy-dpb})\text{Ru}^{III}(\text{tpy-NHOMe})\].

The electronic coupling in \( 6^{+4} \) is in contrast to the amide bridged dinuclear ruthenium complex \([\text{EtOOC-tpy}]\text{Ru}^{III}(\text{tpy-NHCO-tpy})\text{Ru}^{III}(\text{tpy-NHCOME})\] on the same system. The electronic coupling occurs via a superexchange mechanism involving the bridge’s frontier orbitals. 

Emission spectroscopy and triplet excited states of complexes \( 1(PF_6)^{-4}(PF_6) \)

All four mononuclear complexes \( 1(PF_6)^{-4}(PF_6) \) exhibit very weak room temperature emission in the red spectral range (Fig. 6 and Table 2). The carboxy-substituted complexes 3’ and 4’ show the highest energy emission along with the highest phosphorescence quantum yield. Both are in excellent agreement with the values for the methyl ester complex reported by van Koten and coworkers. 

We ascribe this to the decomposition of the highly charged complex \( 6^{+4} \) on the timescale of the measurement (about 45 minutes). The fact, that the NIR band is only present in the mixed-valent state \( 6^{+3} \), allows for the conclusion that it arises from an intervalence charge transfer (IVCT) process between the two metal centers RuII → RuIII. The absorption band in the red spectral region on the other hand is ascribed to ligand-to-metal (LMCT) transitions in the newly formed RuIII fragment (dpb → Ru). This is supported by TD-DFT calculations which predict such a symmetry allowed IVCT transition (dπ(Ru) + dpb-CO → dπ(Ru) + dpb-NH) to occur at a wavelength of 1395 nm and LMCT excitations at around 630 nm for \( 6^{+3} \) (ESI, Table S9). Additionally, the absorption spectra of the mononuclear complexes 1’ and 3’ exhibit very similar LMCT bands in the range between 600 and 800 nm upon oxidation under the same conditions (ESI, Fig. S19). In particular, the excellent agreement between the LMCT maximum of 1’ (720 nm) and \( 6^{+4} \) (716 nm) underlines that the first oxidation of \( 6^{+2} \) occurs at the N-substituted [Ru(dpdb)(tpy)]” fragment.

Although a straight-forward Hush analysis of the band shape and energy of the IVCT band is formally not correct due to the energy difference between the two valence isomers \( [(\text{tpy})\text{Ru}^{III}(\text{dpb-NHCO-dpb})\text{Ru}^{II}(\text{tpy})]\) and \( [(\text{tpy})\text{Ru}^{III}(\text{dpb-NHCO-dpb})\text{Ru}^{II}(\text{tpy})]\), as the donor-acceptor distance \( r_{MM} \) the Ru-Ru distance of 13.1 Å (from DFT calculation) was taken into account despite the fact that the involved orbitals are substantially delocalized towards the cyclometalated bridging ligand, thus rendering the electronic coupling parameter \( V_{ab} \) (ESI, Fig. S20). As the donor-acceptor distance \( r_{MM} \) the Ru-Ru distance of 13.1 Å (from DFT calculation) was taken into account despite the fact that the involved orbitals are substantially delocalized towards the cyclometalated bridging ligand, thus rendering the effective charge transfer distance smaller. 

As using a too large value for \( r_{MM} \) will underestimate the electronic coupling parameter, the calculated \( V_{ab} \) value of 580 cm\(^{-1}\) represents a lower limit. This coupling in \( 6^{+3} \) is roughly half as strong as in the back-to-back linked symmetrical dinuclear complex \( [(\text{tpy})\text{Ru}(\text{dpb-dpb})\text{Ru}(\text{tpy})]\) (tpy = 4-tolylterpyridine). We attribute this weakening to the redox asymmetry introduced by the amide bridge in \( 6^{+4} \). Simultaneously, the NHCO group increases the donor-acceptor distance and reduces the orbital overlap between the two complex moieties. Clearly, the mixed-valent complex \( 6^{+3} \) has to be assigned to the Robin–Day class II with localized valences and a moderate electronic coupling between the complex subunits. The activation barrier for thermal electron transfer can be calculated when the strength of electronic coupling and the energy difference \( \Delta G_0 \) of the two valence isomers are known. The latter can be estimated based on the difference in redox potentials of the RuII/RuIII couple of the two complex subunits. Since for \( 6^{+3} \), this difference is shifted towards larger values due to charge accumulation and the resonance stabilization of the mixed-valent species \( 6^{+4} \), we used the difference in RuII/RuIII redox potentials of the mononuclear complexes 1 and 3’ to estimate \( \Delta G_0 \) as 0.22 eV (1775 cm\(^{-1}\), 21 kJ mol\(^{-1}\)). This yields an activation barrier of the electron transfer from \( [(\text{tpy})\text{Ru}^{III}(\text{dpb-NHCO-dpb})\text{Ru}^{II}(\text{tpy})]\) to \( [(\text{tpy})\text{Ru}^{III}(\text{dpb-NHCO-dpb})\text{Ru}^{III}(\text{tpy})]\) of 2190 cm\(^{-1}\) (26 kJ mol\(^{-1}\)).

The electronic coupling in \( 6^{+3} \) is in contrast to the amide bridged dinuclear ruthenium complex \([\text{EtOOC-tpy}]\text{Ru}^{III}(\text{tpy-NHCO-tpy})\text{Ru}^{III}(\text{tpy-NHCOME})\] on the same system. The electronic coupling occurs via a superexchange mechanism involving the bridge’s frontier orbitals. In the bis(terpyridine)ruthenium system, these are well separated in energy from the donor and acceptor orbitals at the metal centers. Thus, the tunnel barrier for electron transfer is much higher than in \( 6^{+4} \) leading to no detectable electronic interaction in the former. In contrast, the mediating bridge orbitals of \( 6^{+3} \) are already mixed into the ground state donor and acceptor orbitals of the metal centers, significantly increasing the electronic coupling in \( 6^{+3} \). Obviously, cyclometalating bridging ligands enable electronic communication in mixed-valent RuII/RuIII complexes.

Fig. 6 Normalized steady-state emission spectra of 1(PF6)–4(PF6) (λexc = 500 nm) (a) at room temperature in degassed acetonitrile solution, (b) at 155 K in liquid butyronitrile solution and (c) at 77 K in a frozen butyronitrile matrix.

excited state lifetimes at room temperature are well below one nanosecond.

The shape of the emission band of the two COOR-substituted compounds 3* and 4* is very similar to that of many other (polypyridine)ruthenium(II) complexes with a vibronic progression resulting in a typical low-energy shoulder.2,27,31,40 The emission band shape of the 0→0 transition, which typically is quite strong in other [Ru(dpbdtpy)] complexes at room temperature, apparently is of less relevance in complexes with dbp-NHR ligands (ESI, Fig. S21†). Consequently, in a solid butyronitrile matrix at 77 K, a more pronounced hypsochromic shift is observed for complexes 1* (1085 cm⁻¹) and 2* (860 cm⁻¹) than for 3* and 4* (580 cm⁻¹). At 77 K in frozen butyronitrile solution, the carboxy-substituted complexes 3* and 4* emit at a wavelength of 708–709 nm, while the amido- and amino-substituted complexes 1* and 2* emit at 736 and 731 nm, respectively. The similarity in the emission energy of the latter two complexes is remarkable and not straight-forwardly under-
states in which the tpy ligand can be formally regarded as singly reduced while the Ru–dpb moiety carries an electron hole.\(^\text{10}\) This latter low-energy state was considered responsible for the lack of emission from the strongly donor–acceptor substituted complex \([\text{Ru(dpdb-NHCOMe)(tpy-COOEt)}]^+\) because the orthogonality of the orbitals of the electron and hole prevents the radiative recombination from the \(^3\text{LLCT}\) state.\(^\text{40}\)

Remarkably, all triplet states exhibit characteristic distortions compared to the geometry of the respective singlet ground state structures with a strong resemblance between the COOR-substituted complex on one side and the NHR-substituted complex on the other (Fig. 7). In the \(^3\text{MLCT}\) states of complexes \(1^+\) and \(4^+\), the arrangement of the ligand periphery is essentially unaltered while the metal center is shifted towards the tpy ligand. The Ru–N\(^{\text{dpb}}\) central bond length is shortened by 2 pm (\(^1\text{GS}: 204\) pm, \(^3\text{MLCT}: 206\) pm for \(3^+\) and \(4^+\)) while the Ru–C\(^{\text{dpb}}\) bond is elongated by 4 pm in both cases (\(^1\text{GS}: 195\) pm, \(^3\text{MLCT}: 199\) pm for \(3^+\) and \(4^+\)). This is in agreement with an increased coulombic interaction between the formally oxidized Ru and reduced tpy ligands upon population of the \(^3\text{MLCT}\) state and has been described before for other polypyridine ruthenium complexes.\(^\text{35,40}\) All Ru–N bonds involving the four peripheral pyridines are nearly unaffected with similar bond lengths between 210 pm and 212 pm in all cases. This is in stark contrast to the geometry of the \(^3\text{MLCT}\) state of both \(1^+\) and \(2^+\). Here, the ligand periphery is substantially distorted compared to the \(^1\text{GS}\) geometry: the central pyridine ring of the tpy unit is offset from the plane perpendicular to the dpb ligand with a central N\(^{\text{dpb}}\)–Ru–C\(^{\text{dpb}}\) bond angle of just \(167^\circ\). At the same time, one of the two peripheral pyridine rings of the dpb unit is shifted away from the metal center to some extent yielding a long Ru–N bond of 219 pm while the trans Ru–N bond is shortened to 209 pm (from 212 pm in the \(^1\text{GS}\) of \(1^+\) and \(2^+\)). A similar shift of the metal center towards the tpy ligand as observed for \(3^+\) and \(4^+\) is also found for \(1^+\) and \(2^+\). This difference in the geometry of the \(^3\text{MLCT}\) states between the NHR- and COOR-substituted complexes might explain the dominance of 0–2 transitions in the emission spectra of \(1^+\) and \(2^+\) as it corresponds to a larger horizontal offset on the \(^1\text{GS}–^3\text{MLCT}\) reaction coordinate.

In the \(^3\text{LLCT}\) states again a clear distinction is found between the geometries of complexes \(1^+\) and \(2^+\) on one side and \(3^+\) and \(4^+\) on the other. The \(^3\text{LLCT}\) geometries of complexes \(1^+\) and \(2^+\) appear essentially undistorted compared to the \(^1\text{GS}\) structures with a slight elongation of the central Ru–N\(^{\text{dpb}}\) bond by about 4 pm.\(^\text{40}\) A similar shift is observed in the \(^3\text{LLCT}\) states of complexes \(3^+\) and \(4^+\). Yet, in their \(^3\text{LLCT}\) geometries, the tpy ligand is twisted by about \(8^\circ\) out of the plane perpendicular to the dpb ligand.

The \(^3\text{MC}\) states of all four complexes appear structurally similar with immensely elongated bond lengths between Ru and the tpy nitrogen atoms (central Ru–N\(^{\text{dpb}}\) bonds: 225–227 pm, peripheral Ru–N\(^{\text{dpb}}\) bonds: 235–237 pm). This distortion is accompanied by a tilt of the peripheral pyridine rings compared to the central one within the tpy unit by 9–11°. The dpb ligand on the other side is undistorted with typical Ru–dpb bond lengths (central Ru–C\(^{\text{dpb}}\) bonds: 195–196 pm, peripheral Ru–N\(^{\text{dpb}}\) bonds: 215–217 pm).

Based on DFT calculated Gibbs free energies, the \(^3\text{LLCT}\) state is the triplet ground state of the NHR-substituted com-

---

**Fig. 7** Jablonski diagram of the triplet states of complexes \(1^+–4^+\) including DFT spin density plots (B3LYP, def2-SV(P), COSMO (acetonitrile), ZORA; contour value: 0.01). \(^3\text{MLCT}\) energies are given as experimental 0–0 emission energies, \(^3\text{LLCT}\) and \(^3\text{MC}\) energies are calculated based on DFT derived Gibbs free energies relative to the respective \(^3\text{MLCT}\) energy and given in kJ mol\(^{-1}\). Hydrogen atoms are omitted for clarity.
plexes $1^+$ and $2^-$ (Fig. 7) followed by the $3$MLCT and $3$MC states. This order is identical to that of the strongly donor–acceptor substituted complex [Ru(dpb-NHCOMe)(tpy-COOEt)]. In complexes $3^-$ and $4^-$, in which the donor strength of the dpb ligand is weakened by the COOR substituents, the order of $3$MLCT and $3$LL_CT is inverted. Increasing the push–pull substitution of a given heteroleptic [Ru(dpb)(tpy)]$^+$ complex will lower the energy of a donor–acceptor charge-separated state, here the $3$LL_CT state, relative to the other excited states. Remarkably, the trends of the geometrical features of the various states can be related to their relative energies. While for $1^-$ and $2^-$, the $3$LL_CT state is the least distorted compared to the $1$GS geometries, for $3^-$ and $4^-$ this is true for the $3$MLCT state instead.

Considering the relative energies of the various triplet states, it is apparent that the emissive $3$MLCT state is flanked by two non-emissive states ($3$MC and $3$LL_CT) for all four complexes. Both are thermally accessible, instead of just a single state ($3$MC) as in [Ru(bpy)$_3$](PF$_6$)$_2$. The presence of a second non-emissive state at low energy gives rise to an additional excited state deactivation pathway. This is important for the interpretation of the temperature dependence of the emission spectra of $1$(PF$_6$) and $3$(PF$_6$) (Fig. 8). In fact, a second exponential term needs to be taken into account, compared to Meyer’s original equation which accounts for a single depopulating state. Including a second state yields the following equation (for derivation see the ESI):

$$\ln(\phi) = \ln(k_1) - \ln(k_2 + k_{nr} + k_1 \exp(-\Delta E_1/RT) + k_2 \exp(-\Delta E_2/RT)).$$

The rate constants $k_1$ and $k_{nr}$ describe the radiative and non-radiative decays ($3$MLCT $\rightarrow$ $1$GS), $\Delta E_1$ corresponds to the activation barrier for surface crossing from the $3$MLCT to the $3$MC state ($\Delta E_1 = \Delta G_1^-$) and $k_1$ is the rate constant for this surface crossing at infinite temperature as shown by Meyer.

An analogous equation was previously used by Balzani and coworkers to describe the photodynamics of complexes of the [Ru(bpy)$_3$]$_2^+$ family. In these cases, $\Delta E_1$ corresponds to the barrier for the thermally activated $3$MLCT $\rightarrow$ $3$MC surface crossing while $\Delta E_2$ (typically $<1$ kJ mol$^{-1}$) is interpreted as the energy separation between multiple close-lying $3$MLCT states split by spin–orbit coupling.

In the present study, $\Delta E_2$ can be interpreted either as the energy difference $\Delta G_0$ of the $3$MLCT and $3$LL_CT states in thermal equilibrium or the activation barrier $\Delta G_1^-$ for the surface crossing from the $3$MLCT to the $3$LL_CT state (see the ESI† for in-depth elaboration). This depends on the relative rate constants for the reverse internal conversion $3$LL_CT $\rightarrow$ $3$MLCT and the non-radiative intersystem crossing (ISC) to the ground state ($3$LL_CT $\rightarrow$ $1$GS). Upon cooling of solutions of all four mononuclear complexes, even complexes $1^-$ and $2^-$, in which the emissive $4$MLCT state is not the triplet ground state, the emission intensity increases. This corroborates that $3$MLCT and $3$LL_CT cannot be in thermal equilibrium at least in complexes $1^-$ and $2^-$. For complexes $3^-$ and $4^-$, this conclusion cannot be drawn purely based on the temperature dependence of the emission quantum yield, since both, the energy difference of the $3$MLCT and $3$LL_CT states and the activation barrier $\Delta G_1^-$ are positive. Based on the DFT calculated energies of the activation barriers for the $3$MLCT–$3$LL_CT surface crossing and the experimentally determined $\Delta E_2$ values (vide infra), however, it is plausible, that also for complexes $3^-$ and $4^-$, the surface crossing into the $3$LL_CT state is irreversible and followed by rapid relaxation into the singlet ground state. Consequently, $\Delta E_2$ is identified in analogy to $\Delta E_1 = \Delta G_1^-$ as the activation barrier $\Delta G_2^-$ for the thermal depopulation of the $3$MLCT via the $3$LL_CT states.

Based on the very similar 0–0 emission energies which should give similar rate constants for the non-radiative decay ($3$MLCT $\rightarrow$ $1$GS), the large differences in the phosphorescence quantum yields of the four complexes $1^–4^-$ are quite unexpected (Table 2). Yet, combining the $\ln(\phi)$ vs. $T^{-1}$ plots with the relative energies of the involved states as determined by DFT provides an explanation. For complexes $3^-$ and $4^-$ the
relatively high quantum yield is associated with the emissive \(^3\)MLCT state being the triplet ground state. For \(1^+\) and \(2^+\) on the other hand, the non-emissive \(^3\)LL'CT state becomes the triplet ground state giving rise to a deactivation pathway with a potentially very low activation barrier \(\Delta G^1\). Due to the small experimentally accessible temperature range, the fit using the biexponential equation given above is overparametrized. Consequently, quantitative results have to be considered very carefully. For \(1^+\), activation barriers of \(\Delta G^1 = 21.7 \text{ kJ mol}^{-1}\) and \(\Delta G^2 = 2.1 \text{ kJ mol}^{-1}\) are obtained from the fit, while for \(3^+\), the activation barriers are \(\Delta G^1 = 23.1 \text{ and } \Delta G^2 = 6.2 \text{ kJ mol}^{-1}\). Based on the calculated energies of the various triplet states (Fig. 7), it is reasonable to assume that the higher activation barriers \(\Delta G^1\) of >20 kJ mol\(^{-1}\) are associated with the deactivation via the \(^3\)MC state (\textit{vide infra}). \(\Delta G^2\) is very similar for both the NHR- and COOR-substituted complex types, corroborating that the substitution pattern at the cyclometalating ligand only has a marginal effect on the ligand field splitting in the \([\text{Ru(dpdb-R(tpy)}]^+\) type of complexes. The second activation barrier \(\Delta G^2\) of \(1^+\) is only one third of that of \(3^+\). Hence, thermal deactivation via \(^3\)LL'CT states is significantly accelerated by the presence of an electron donating substituent at the dpb ligand explaining the substantially lower quantum yield of the former. Substituents at the tpy ligand on the other hand are expected to influence both activation barriers but especially \(\Delta G^1\) between the \(^3\)MLCT and \(^3\)MC states since the substituents at the tpy ligand significantly impact the \(^3\)MLCT energy.

To gain a better understanding of the excited state processes, we performed DFT based geometry optimizations to find the transition states connecting the \(^3\)MLCT and the \(^3\)MC states on one side and the \(^3\)MLCT and \(^3\)LL'CT states on the other. All four transition states could be localized successfully and their nature confirmed by the presence of a single negative vibrational frequency representing the reaction coordinate of the respective transition (Fig. 9). Subsequent spin density calculations further confirmed the nature of the localized states as the desired transition states. For both complexes, \(1^+\) and \(3^+\), the spin density of the \(^3\)MLCT-\(^3\)LL'CT transition state shows contributions of both ligands and, predominantly, the metal center. Remarkably, the spin carrying orbital at the metal center neither corresponds to the \(d_{yz}\) orbital as in the \(^3\)MLCT state nor to the \(d_{xz}\) orbital as in the \(^3\)LL'CT state but is a linear combination of both. This further underlines the transition state character of the localized state. Similarly, the \(^3\)MLCT-\(^3\)MC transition states of \(1^+\) and \(3^+\) show a substantial amount of spin density at the metal center (1.46 electrons based on Mulliken's spin population analysis). But instead of the nitrogen lone pairs, a tpy \(\pi^*\)-orbital (LUMO of \(1^+\) and \(3^+\)) contributes to this transition state. The DFT calculated transition state energies \(\Delta G^1\) (DFT) and \(\Delta G^1\) (exp.) and \(\Delta G^2\) (exp.) extracted from the fits of the \(\ln(\phi)\) vs. \(T^{-1}\) plots show remarkable agreement with deviation as small as \(\pm 2 \text{ kJ mol}^{-1}\). This suggests that despite the narrow temperature range of the VT measurement and their very low quantum yields and short excited state lifetimes, a very reasonable description of the excited state deactivation processes can be obtained for these cyclometalated complexes.

In summary, dpb ligands in bis(tridentate)ruthenium(II) complexes indeed induce high-energy \(^3\)MC states, but give rise to low-energy \(^4\)LL'CT states. As for both states, emission is symmetry-forbidden, both contribute to the rapid excited state deactivation observed for these types of complexes. The combination of two \([\text{Ru(dpdb)}(tpy)]^+\) emitters is discussed in the next chapter.

**Emission spectroscopy and triplet excited states of complex 6(PF\(_6\))**

For the dinuclear complex \(6^{2+}\), a broadened emission spectrum is obtained at room temperature compared to the formally constituting mononuclear complexes \(1^+\) and \(3^+\) (Fig. 10). Additionally, the position of the emission maximum is dependent on the excitation wavelengths and shifts from 756 nm upon excitation at 480 nm to 772 nm when being irradiated at 560 nm (Fig. 10 and Table 2). Measurement at 155 K in butyronitrile yields substantially sharpened emission spectra with an emission maximum at 746 nm and a pronounced shoulder at 800 nm. The intensity of this shoulder increases upon increasing the excitation wavelength from 480 to 560 nm. The blue-shift of the emission maximum (180 cm\(^{-1}\)) upon freezing the butyronitrile solution of \(6^{2+}\) is much smaller than that of all mononuclear complexes under study.
A wavelength dependence of the emission maximum from the excitation energy is very atypical for polypyridineruthenium(II) complexes. We ascribe this behaviour to two independent emission processes in solution involving the two complex subunits of $6^2$+. In fact, similar dual emission processes have previously been invoked to explain the emission wavelength dependence from the excitation energy. Unfortunately, attempts to measure the excited state lifetimes by time-correlated single photon counting failed in this case due to the very rapid excited state decay of $6^2$+. Hence, no evidence for a bieponential character of the excited state decay, which would support the presence of a dual emission mechanism, could be obtained.

However, a reasonable explanation for the dual emission of $6^2$+ can be given based on its absorption characteristics. As shown above, the visible range of the absorption spectrum of $6^2$+ is composed of $1^{\text{MLCT}}$ excitations localized on one of the two complex halves. Upon intersystem crossing and vibrational relaxation, $\text{d}_{\text{c}}(\text{Ru}) \rightarrow \text{tpy} \text{ } 3^{\text{MLCT}}$ states are populated. Two such triplet excited states are conceivable, namely $\text{[(tpy)}^{\text{−}}\text{Ru}^{\text{II}}(\text{dpb-NHCO-dpb})\text{Ru}^{\text{III}}(\text{tpy})]^{2+}$ and $\text{[(tpy)}\text{Ru}^{\text{II}}(\text{dpb-NHCO-dpb})\text{Ru}^{\text{III}}(\text{tpy}^{\text{−}})]^{2+}$, with the triplet spin density localized on opposing [Ru(tpy)] fragments (ESI, Fig. S24†). Via double electron transfer from Ru$^{\text{II}}$ to Ru$^{\text{III}}$ and from tpy$^{\text{−}}$ to tpy (Dexter energy transfer), these states could interconvert. According to the large distance between the two [Ru(tpy)] moieties ($\text{RuRu} = 13$ Å, $r_{\text{tpy,tpy}} \approx 20$ Å), Dexter energy transfer, whose rate constant decays exponentially with distance, is rather slow between the complex subunits. All other radiative and non-radiative relaxation pathways of triplet $6^2$+ are extremely fast (below 1 ns as evidenced from time-resolved emission spectroscopy). Consequently, in fluid solution, emission occurs faster than thermal equilibration between the two emissive $3^{\text{MLCT}}$ states. If equilibration was faster than emission, the $\text{[(tpy)}^{\text{−}}\text{Ru}^{\text{II}}(\text{dpb-NHCO-dpb})\text{Ru}^{\text{III}}(\text{tpy}^{\text{−}})]^{2+}$ state would be favoured over $\text{[(tpy)}\text{Ru}^{\text{II}}(\text{dpb-NHCO-dpb})\text{Ru}^{\text{III}}(\text{tpy})]^{2+}$ thermodynamically and would yield single emission at around 800 nm, but this is not observed.

Given that the two $3^{\text{MLCT}}$ states are not in thermal equilibrium, it should be possible to selectively populate one or the other excited state by irradiation into one of the two complex subunits. Since in the absorption spectrum of $6^2$+ the absorption bands of the two fragments [tpy]Ru(dpdb-NHNR) and [(ROC-dpb)Ru(tpy)] overlap substantially, it is not possible to excite them with 100% selectivity (Fig. 4). But by changing the excitation wavelength it is possible to gradually tune the ratio at which the two building blocks are excited. The difference spectrum of the two mononuclear complexes $1^1$ and $3^1$ carrying similar functional groups as the two subunits of $6^2$+ (Fig. 4) gives an idea where a maximum difference of absorption can be expected between the NH- and CO-substituted [Ru(dpdb)(tpy)] complex subunits. This difference spectrum reveals a maximized and minimized absorption of the COR-substituted complex at around 480 and 560 nm, respectively. This is in excellent agreement with the above mentioned minimum and maximum of the shoulder at 800 nm in the emission spectrum of $6^2$+ at 155 K. Additionally, the difference spectrum of the emission spectra recorded at 155 K with $\lambda_{\text{exc}} = 480$ and 560 nm reveals a band with a maximum at 800 nm (ESI, Fig. S25†) that resembles the emission band of $1^1$ at that temperature (Fig. 6b). These observations strongly support that dual emission occurs from two uncoupled $3^{\text{MLCT}}$ excited states of the dinuclear complex $6^2$+ in solution.

The origin of this dual emission process is markedly different than that observed for the structurally similar amide-bridged dinuclear complex [[EtOOC-tpy]Ru(tpy-NHCO-tpy) Ru(tpy-NHCOMe)]$^{44,55}$ in the latter, the involved emissive states are sufficiently long-lived and at a significantly shorter distance to allow for thermal equilibration prior to emission. Since the emissive states [[EtOOC-tpy]Ru$^{\text{II}}$(tpy-NHCO-tpy)$^\text{−}$] Ru$^{\text{III}}$(tpy-NHCOMe)$^{44}$ and [[EtOOC-tpy]Ru$^{\text{II}}$(tpy-NHCO-tpy)$^\text{−}$] Ru$^{\text{III}}$(tpy-NHCOMe)$^{44}$ are very similar in energy, occupation between the two is Boltzmann distributed leading to dual emission at room temperature.

Interestingly, upon freezing of the butyronitrile solution of $6^2$+, single emission is observed arising from the NHR-substituted subunit as judged from the position of the emission maximum as well as the independence of the emission band shape from the excitation wavelength (Fig. 10c). This loss of
Experimental

General procedures

Chemicals were obtained from commercial suppliers and used without further purification. Air- or moisture-sensitive reactions were performed in dried glassware under an inert gas atmosphere (argon, quality 4.6). Acetonitrile was refluxed over CaH₂ and distilled under argon prior to use. The ligands N-acetyl-3,5-dipryrid-2'-ylalanine L₁ and ethyl 3,5-dipryrid-2'-ylbenzoate L₂ as well as RuCl₃(tpy) were synthesized following the literature-known procedures. Infrared spectra were recorded on a Varian Cary Eclipse spectrometer. Quantum yields were determined by comparing solutions of the samples and a reference with solvent effects, a conductor-like screening model (COSMO) modelling acetonitrile was used in all calculations. The ZORA keyword automatically invokes relativistically adjusted basis sets. To account for solvent effects, a conductor-like screening model (COSMO) modelling acetonitrile was used in all calculations. TD-DFT calculations with at least 50 vertical transitions were carried out based on the def2-SVP optimized geometry of the respective complex. Explicit counterions and/or solvent molecules were not taken into account in all cases. To reduce the computational cost, methyl instead of ethyl groups at the ester moiety were used throughout all calculations.

Synthesis of [Ru(dpb-NHCOCH₃)(tpy)](PF₆) (1). RuCl₃(tpy) (250 mg, 0.567 mmol, 1 eq.) and AgBF₄ (320 mg, 1.64 mmol, 2.9 eq.) were dissolved in dry acetone (20 ml) and heated to reflux for 16 h to give a dark purple solution. The resulting mixture was heated to reflux for 16 h to give a dark purple solution. Upon addition of more water (80 ml), a black solid precipitated which was filtered off. Column chromatography on silica gel (CHCl₃: MeOH = 7:1) afforded [Ru(dpb-NHCOCH₃)(tpy)]PF₆ (1) as a dark purple solid. Yield: 175 mg (0.228 mmol, 40%). Anal. Calc. for C₃₃H₂₅N₆ORu[P(F₆)]₂: C, 50.45; H, 3.46; N, 10.70. Found: C, 50.62; H, 3.31; N, 10.46. MS(ESI+, m/z = 623.1 (100) [M – PF₆]⁺; HR-MS(ESI⁺, m/z): m/z (%) = 623.1 (100) [M – PF₆]⁺. For [Ru(tpy)(H₂O)]²⁺ as the supporting electrolyte in acetonitrile. The potentials are given relative to the ferrocene/ferriocenium couple (0.40 V vs. SCE, E₁/₂ = 0.09 ± 5 mV under the given conditions).72

Density functional theory calculations

DFT calculations were carried out using the ORCA program package (version 3.0.2). Tight convergence criteria were chosen for all calculations (keywords TightSCF and TightOpt, convergence criteria for the SCF part: energy change 1.0 × 10⁻⁶ Eₜₙ, 1-El. energy change 1.0 × 10⁻⁵ Eₜₙ, orbital gradient 1.0 × 10⁻⁳, orbital rotation angle 1.0 × 10⁻³, DIIS error 5.0 × 10⁻⁵; for geometry optimizations: energy change: 1.0 × 10⁻⁶ Eₜₙ, max. gradient 1.0 × 10⁻⁴ Eₜₙ per bohr, RMS gradient 3.0 × 10⁻⁵ Eₜₙ per bohr, max. displacement 1.0 × 10⁻³ bohr, RMS displacement 6.0 × 10⁻⁴ bohr). All calculations employ the resolution of identity (Split-Rhf) approach for the coulomb term in combination with the chain-of-spheres approximation for the exchange term (COSX). All calculations were performed using the hybrid functional B3LYP in combination with Ahlrichs' split-valence double-ξ basis set def2-SVP(P) which comprises polarization functions for all non-hydrogen atoms. Relativistic effects were calculated at the zeroth order regular approximation (ZORA) level.77 The ZORA keyword automatically invokes relativistically adjusted basis sets. To account for solvent effects, a conductor-like screening model (COSMO) modelling acetonitrile was used in all calculations. Explicit counterions and/or solvent molecules were not taken into account in all cases. To reduce the computational cost, methyl instead of ethyl groups at the ester moiety were used throughout all calculations.
the residue was dissolved in a minimal amount of acetonitrile (5 ml) followed by addition of a solution of NH4PF6 (153 mg, 0.939 mmol, 6.75 eq.) in water (80 ml). The precipitate was filtered off and washed with water (2 × 5 ml) and diethyl ether (2 × 15 ml) giving [Ru(dpdb-NH2)(tpy)](PF6) as a purple solid. Yield: 92 mg (0.127 mmol, 86%). Anal. Calc. for C34H26F6N5O2PRu (782.6): C, 52.01; H, 3.34; N, 8.65. MS(ESI+): [M−PF6]−: 575.1060; Found: 575.1071. 1H NMR (CD3CN): δ [ppm] = 217.2 (C9B), 169.6 (C10B), 159.8 (C4A), 155.4 (C3A), 153.5 (C8A), 152.8 (C6B), 143.1 (C3A), 136.7 (C6B), 136.4 (C4A), 133.8 (C3A), 127.3 (C7A), 124.6 (C8B), 124.5 (C6A), 123.3 (C2A), 120.9 (C19), 61.5 (C11), 14.9 (C12). IR (KBr disk): ν [cm−1] = 1695 (s, C=O ester), 1600, 1582 (m, C=C), 843 (s, P-F).

Synthesis of [Ru(dpdb-COOH)(tpy)](PF6) 4(PF6). [Ru(dpdb-COOCH3)(tpy)](PF6) 3(PF6) (154 mg, 0.197 mmol) was added to a mixture of water (20 ml), methanol (20 ml), hydrazine monohydrate (1 ml) and sodium hydroxide (1 g) and heated to reflux for 16 h. After removal of the solvent under reduced pressure, the dark residue was dissolved in a minimal amount of acetonitrile (5 ml) followed by addition of a solution of NH4PF6 (145 mg, 0.890 mmol, 4.5 eq.) in water (40 ml) and the product precipitated. The complex was filtered off and washed with water (2 × 5 ml) and diethyl ether (2 × 15 ml). Column chromatography on silica gel (CHCl3: MeOH = 5 : 1) afforded [Ru(dpdb-COOH)(tpy)](PF6) 4(PF6) as a dark red solid. Yield: 82 mg (0.109 mmol, 55%). Anal. Calc. for C32H22F6N5O2Pru (754.6): C, 50.93; H, 2.94; N, 9.28. Found: C, 50.64; H, 2.51; N, 9.42. MS(ESI+): m/z (%) = 610.1 (100) [M − PF6]−. HR-MS(ESI+): m/z: Calcd for C32H22F6N5O2Pru [M − PF6]−: 604.0849; Found: 604.0873. 1H NMR (CD3CN): δ [ppm] = 8.85 (s, 2H, H3A), 8.74 (d, 2H, JHH = 8 Hz, H5A), 8.42 (d, 2H, JHH = 8 Hz, H8A), 8.30 (t, 1H, JHH = 8 Hz, H11A), 8.27 (d, 2H, JHH = 8 Hz, H11B), 7.74–7.56 (m, 4H, H8A,H 8B), 7.33–7.24 (m, 2H, H7B). 13C{1H} NMR (CD3CN): δ [ppm] = 169.5 (C9B), 159.8 (C4A), 155.5 (C3A), 152.8 (C6B), 143.2 (C3A), 136.7 (C6B), 136.4 (C4A), 133.9 (C3A), 127.4 (C7A), 125.0 (C8B), 124.6 (C8A), 124.3 (C4A), 123.1 (C2A), 122.4 (C19), 121.0 (C11B), 24.3 (C11). IR (KBr disk): ν [cm−1] = 3340 (s, O-H acid), 1665 (s, C=O acid), 1602, 1579 (m, C=C), 843 (s, P-F).

Synthesis of [Ru(dpdb-COOCH3)(tpy)](PF6) 5(PF6). [Ru(dpdb-COOCH3)(tpy)](PF6) 3(PF6) (42 mg, 0.056 mmol, 1 eq.), N,N-diisopropylcarbodiimide (15 mg, 0.119 mmol, 2.1 eq.) and N-hydroxybenzotriazole (HOBt, 18 mg, 0.117 mmol, 2.1 eq.) were dissolved in dry acetonitrile (20 ml) and stirred for 16 h at room temperature. After removal of the solvent under reduced pressure, the dark residue was dissolved in acetonitrile (5 ml). The product was precipitated by addition of NH4PF6 (95 mg, 0.583 mmol, 10.4 eq.) and water (50 ml), filtered off and washed with water (2 × 5 ml) and diethyl ether (2 × 15 ml). [Ru(dpdb-COOCH3)(tpy)](PF6) 5(PF6) was obtained as a dark red solid. Yield: 45 mg (0.052 mmol, 92%). Anal. Calc. for C34H22F6N5O2Pru (871.69): C, 52.36; H, 2.89; N, 12.85.
Found: C, 52.42; H, 2.53; N, 12.54. MS(ESI\(^{+}\): m/z (%) = 699.1 (11) [M – PF\(_6\) – N\(^{2+}\)] , 727.1 (100) [M – PF\(_6\)\(^2+\)] , 1599.2 (8) [2M – PF\(_6\)\(^2+\)]. **Synthesis of \([\text{tpy}]\text{Ru(dpb-NHCO-dpb)}\text{tpy}(\text{PF}_6)_{2}\) and \([\text{tpy}]\text{Ru(dpb-NHE-dpb)}\text{tpy}(\text{PF}_6)_{2}\).**

In separate Schlenk flasks, \([\text{Ru(dpb-NH}_{2}\text{tpy})\text{(PF}_6)]\) (2P\(_{F6}\)) (35 mg, 0.048 mmol, 1 eq.) and \([\text{Ru(dpb-COObt-tpy})\text{(PF}_6)]\) (5P\(_{F6}\)) (42 mg, 0.048 mmol, 1 eq.) were dissolved in dry acetonitrile (10 ml). Molecular sieves (3 Å) were added and the mixtures were left to stand overnight to remove crystal water. Both solutions were then combined in a third Schlenk flask and a further portion of \(\text{Ru(dpb-NH}_{2}\text{tpy})\text{(PF}_6)]\) (11) P\(_{F6}\) (35 mg, 0.048 mmol, 1 eq.) was added. The resulting solution was stirred at 50 °C. After quenching the reaction by addition of \(\text{NH}_2\text{PF}_6\) (180 mg, 1.10 mmol, 23 eq.) dissolved in water (2 ml), the solution was concentrated to 5 ml and the product was triturated by addition of water (80 ml). The precipitate was filtered off, washed with water (2 x 5 ml) and diethyl ether (2 x 15 ml) and purified by column chromatography on silica gel (CH\(_2\)Cl\(_2\): MeOH = 7:1) affording \([\text{tpy}]\text{Ru(dpb-NHCO-dpb)tpy}(\text{PF}_6)_{2}\), \([\text{tpy}]\text{Ru(dpb-NHE-dpb)tpy}(\text{PF}_6)_{2}\) as a dark red solid. Yield: 14 mg (0.0096 mmol, 20%).

**Conclusions**

The electrochemical, UV-Vis and excited state properties of a series of \([\text{Ru(dpb-R)(tpy})\text{]}\) type complexes was systematically studied. The visible range absorption bands of these complexes are dominated by two electronically decoupled \(^{1}\)MLCT transitions either involving the dpb ligand (d\(_{pb}\)Ru → dpb) or the tpy ligand (d\(_{tpy}\)Ru → tpy). These excitations are followed by intersystem crossing populating an emissive \([\text{Ru(tpy)}\text{]}\) \(^{3}\)MLCT state in all cases. This study, however, is rapidly depopulated at room temperature via two additional low-energy triplet excited states yielding very low luminescence quantum yields and short excited state lifetimes. VT steady-state emission spectroscopy and extended DFT calculations revealed their nature as \(^{3}\)LLCT and \(^{3}\)MC states yielding a bi-exponential dependence of the quantum yield on the temperature. While the \(^{3}\)MC state has been known as a parasitic channel for non-radiative decay in (polypyridine)ruthenium(II) complexes for over 30 years, the observation of a \(^{3}\)LLCT state in such ruthenium complexes is unprecedented to the best of our knowledge. We previously referred to the \(^{3}\)LLCT state as a spectroscopically undetectable state ("dark" state). However, the characteristic temperature dependence of the quantum yield clearly is spectroscopic evidence for its presence. Also for the bis(tridentate)iridium(III) complex, the \(^{3}\)MC state with its absorption in the visible range is a parasitic state that has a long lifetime and is not coupled to the \(^{3}\)LLCT state. The \(^{3}\)MC state is suggested to be responsible for its low luminescence quantum yield. Based upon the findings of this study, we believe that the excited state deactivation in this cyclometalated iridium complex occurs in an analogous manner via thermal depopulation of the emissive state via \(^{3}\)LLCT states.

Remarkably, for the acceptor-substituted complexes 3’ and 4’, the \(^{3}\)LLCT state resides higher in energy than the \(^{3}\)MLCT state, while for the donor-substituted complexes 1’ and 2’, it is found to be the lowest triplet state. As a consequence, faster deactivation of the emissive \(^{3}\)MLCT states is observed in the latter complexes associated with substantially lowered emission quantum yields compared to complexes 3’ and 4’. But, since emission is observed for 1’ and 2’ with increasing temperature, deactivation via the \(^{3}\)LLCT state is a thermally activated process and the \(^{3}\)MLCT and \(^{3}\)LLCT states are not in thermal equilibrium.

Upon oxidation of the dinuclear complex \(6^{2+}\) to its mixed-valent counterpart \(6^{3+}\), an intense NIR band is detected indicating a photochemical Ru\(^{3+}\) → Ru\(^{3+}\) charge transfer across the asymmetric bis(cyclopentadienyl)bridging ligand. Despite the substantial redox asymmetry of the two complex subunits bearing NH- and CO-substituents, a strong electronic communication between the donor and acceptor sites of the \(6^{3+}\) is observed. In the excited state of \(6^{3+}\) observed, the two complex fragments appear electronically uncoupled with dual emission occurring from \(6^{3}\)MLCT states localized at the two remote \([\text{Ru(tpy)}\text{]}\) moieties. This “anti-Kasha” behaviour is explained based on the long metal–metal distance and the very rapid excited state decay (emissive and non-emissive) that prevents thermal equilibration in solution via energy transfer entirely.
Just upon freezing of the solution, the excited states become sufficiently long-lived to allow for thermalization, so that Kasha’s rule is obeyed.

In summary, we were able to show spectroscopically and computationally that the introduction of N–C=N cyclometalating ligands in bis(tridentate)ruthenium(II) complexes gives rise to low-lying 3LL/CT states that allow for efficient thermal depopulation of the emissive 3MLCT state. Furthermore, we believe that the existence of 3LL/CT states in polypyridine transition metal complexes is more general. As their energy is strongly dependent on the substitution pattern, they become particularly relevant in strong push–pull systems and can interfere with luminescence processes and shorten the excited state lifetimes substantially.

Additionally, in mixed-valent dinuclear ruthenium complexes such as 63+, the biscyclometalating bridge was shown to be an excellent mediator for photochemical electron transfer between the redox sites even in the presence of a substantial redox asymmetry. The triplet excited states of 63-, however, are electronically uncoupled due to the large spatial separation of the emissive [Ru(tpy)] moieties and their short excited state lifetimes induced by the cyclometalating bridge.
