Efficient solar cells are more stable: the impact of polymer molecular weight on performance of organic photovoltaics†

Z. Ding,^{‡a} J. Kettle,^{‡*a} M. Horie,^b S. W. Chang,^b G. C. Smith,^c A. I. Shames^d and E. A. Katz^{ef}

The principle remaining challenge in the research area of organic photovoltaic (OPV) materials is to develop solar cells that combine high efficiency, stability and reproducibility. Here, we demonstrate an experimental strategy which has successfully addressed this challenge. We produced a number of samples of the highly efficient PTB7 polymer with various molecular weights ($M_n \sim 40\text{--}220\text{k}$). OPV cells fabricated with this polymer demonstrated significant improvement of the cell efficiency (by $\sim 90\%$ relative) and lifetime (by $\sim 300\%$ relative) with the M_n increase. We attribute these effects to the lower density of recombination centers (persistent radical defects revealed by EPR spectroscopy) and better photoactive layer morphology in the samples with higher M_n . Relevance of the observed correlation between the OPV efficiency and stability is discussed.

1. Introduction

Organic photovoltaics (OPVs) using a bulk heterojunction (BHJ) structure show promise as an alternative to inorganic semiconductors for solar electricity production and have shown power conversion efficiencies (PCE) in excess of 10%.¹ Much of this success has come with conjugated polymer/fullerene combinations *via* optimization of polymer design and device fabrication procedures.^{2–4} Though the operational lifetime of OPVs is much shorter than that of commercial inorganic PV (~ 25 years for Si devices), significant progress has been made in improving the stability of OPVs.⁵ However, the greatest challenge in this research area is to develop OPV devices combining high efficiency and stability. Indeed, the record outdoor operational lifetime of ~ 2 years was demonstrated for low-efficient

devices (P3HT-PCBM BHJ devices with PCE $\sim 1\%$).⁶ On the other hand, poly{[4,8-bis[(2-ethylhexyl)oxy]benzo[1,2-*b*:4,5-*b'*]dithiophene-2,6-diyl}{3-fluoro-2-[(2-ethylhexyl)carbonyl]thieno[3,4-*b*]thiophenediyl} (PTB7), an attractive low bandgap polymer,⁷ is found to exhibit PCE over 7% when blended with the fullerene derivative [6,6]-phenyl C₇₁-butyric acid methyl ester (C₇₁-PCBM)⁸ but suffers from poor stability.^{9–11}

Another vital drawback of polymer OPVs is poor reproducibility of the physical and electronic properties of polymer-based semiconductors. Different samples of the same polymer might differ by the molecular weight, amount of defects and residual impurities, and consequentially, different polymer batches might perform quite differently in OPV devices.¹² To resolve this limitation an extensive experimental program with a wide international cooperation is currently planned.¹³

Recently, Troshin *et al.* suggested that Electron Paramagnetic Resonance (EPR) spectroscopy is a very powerful tool for assessment of the quality of different conjugated polymers used as the electron donor in OPV¹² and monitoring their photochemical and thermal degradation.¹¹ It has been shown that different batches of the same conjugated polymer might contain substantially different amounts of radical species behaving as traps for mobile charge carriers. Indeed, a correlation between the concentrations of radicals in various batches of conjugated polymers and PCE of the OPV cells on their basis has been revealed.¹² Furthermore, the relative stability of materials was suggested to be quantified from the rates of radical accumulation estimated from their EPR spectra.¹¹

In this paper, we present photovoltaic performance and lifetime of OPV devices fabricated with PTB7 synthesized by various methods or using different commercial sources. We

report that the increase in polymer molecular weight results in decrease of the density of radical defects in the material and corresponding improvement of efficiency and stability of PTB7-based solar cells. We suggest that this relationship may also apply to other conjugated polymers. Furthermore, the study of various grades of the same polymer allows us to postulate a general rule: namely, a more efficient cell should be more stable. Indeed, photoinduced degradation of PV devices under operation is caused by sunlight. The larger the proportion of the incident sunlight power that is converted to electrical power, the smaller the part remaining for activation of degradation. This positive conclusion may be very important for future development of next generation PV.

2. Experimental

2.1 Synthesis of PTB7

2,6-Bis(trimethyltin)-4,8-bis(2-ethylhexyl)benzo[1,2-*b*:3,4-*b'*]dithiophene (66.6 mg, 0.085 mmol) and 2-ethylhexyl-4,6-dibromo-3-fluorothieno[3,2-*c*]thiophene-2-carboxylate (40.0 mg, 0.085 mmol) were dissolved in 0.96 mL *p*-xylene and 0.24 mL dimethylformamide (DMF) in a 5 mL Schlenk tube. Tris(dibenzylidenacetone)palladium(0) (2.3 mg, 0.003 mmol, 5 mol%) was added, and the reaction was stirred at 120 °C for 5.5 hours. Then 0.2 mL 4-bromoanisole was added and stirred at 120 °C for an hour. The resulting mixture was precipitated into a mixture of methanol (100 mL)/37% HCl aqueous solution (2 mL). The precipitate was washed by Soxhlet extraction with ethanol for one day followed by a further day with methylethylketone (MEK), and then extracted with CHCl₃. The solution was filtered through a silica gel column (*ca.* 1 cm of silica gel in height). The chloroform solutions of the polymer were re-precipitated into methanol and then collected using centrifugation at 6000 rpm for 1 minute. The precipitates were dried in vacuum to yield deep blue powder **PTB7-1** (57 mg, 89% yield). GPC: $M_n = 41\ 200$, $M_w/M_n = 2.55$.

Similar procedure was applied using tetrakis-(triphenylphosphine)palladium(0) (2.0 mg, 0.003 mmol, 5 mol%) to yield deep blue powder **PTB7-3** (63 mg, 98% yield). GPC: $M_n = 108\ 900$, $M_w/M_n = 2.56$. **PTB7-1** obtained from Pd₂(dba)₂ catalyst showed lower molecular weight of $M_n = 41k$ than that of **PTB7-3** obtained from Pd(PPh₃)₄ catalyst ($M_n = 109k$). The commercial polymers **PTB7-2** and **PTB7-4** showed relatively high molecular weight of $M_n = 83k$ and very high molecular weight of $M_n = 216k$, respectively.

Polymer purification was carried out using the same approach adopted in an earlier paper.¹⁴ Impurity levels were measured using elemental analysis and content of the main impurities (P, B and Pd) were measured to be <0.3% (the measureable limit for our equipment).

2.2 Material characterisation

Molecular weight and polydispersity index (PDI) of the polymers were measured by gel permeation chromatography (GPC) using THF as an eluent and polystyrene standards. The optical and electrochemical properties of the polymers were examined by

UV-vis absorption spectroscopy and cyclic voltammetry (CV). CV of the polymer films was performed on Pt plate in MeCN solution containing 0.10 M *n*-Bu₄NPF₆ with scan rate of 0.10 V s⁻¹.

2.3 EPR measurements

Room temperature (RT, $T = 295$ K) EPR measurements were done on both polycrystalline and thick film PTB7 samples using a EMX-220 X-band ($\nu = 9.4$ – 9.8 GHz) spectrometer (Bruker Biospin, Rheinstetten, Germany) equipped with a Bruker ER 4102ST rectangular TE₁₀₂ resonator and an Agilent 53150A frequency counter. Densities of paramagnetic centers N_s were determined by comparison of doubly integrated intensities of EPR lines from the samples under study with the intensity of the ERP signal of the purified 5 nm detonation nanodiamond powder with known density of $S = 1/2$ paramagnetic centers $N_s = 6.3 \times 10^{19}$ spin per g.¹⁵ Bruker's WIN-EPR and SimFonia as well as Origin (OriginLab Corp., Northampton, USA) software were used for processing and simulation of EPR spectra.

Dark EPR spectra were measured on both initial polymer powders and films deposited on Si substrate. Prior to measurements all samples were kept under nitrogen atmosphere and in dark conditions. EPR spectra of PTB7 powders were recorded at the following instrumental conditions: non-saturating microwave power $P_{MW} = 0.2$ mW, 100 kHz magnetic field modulation amplitude $A_{mod} = 0.03$ mT, receiver gain $= 2 \times 10^5$, number of coherent acquisitions $n_{aqc} = 25$. In Fig. 1(a) peak-to-peak intensities of these spectra are normalized per 1 mg and, thus, reflect real spin densities in the samples under study. Due to both smaller effective weights of the polymer films as well as strong non-resonance absorption of microwave by the silicon substrate, the PTB7 film samples provide significantly less intensive EPR signals. For better accuracy of spin density estimation EPR spectra of films as well as the corresponding detonation nanodiamond

Fig. 1 (a) X-band RT dark EPR spectra of PTB7 powders recorded at $P_{MW} = 0.2$ mW, $A_{mod} = 0.03$ mT, receiver gain $= 2 \times 10^5$, $n_{aqc} = 25$ and $\nu = 9.755$ GHz. Background signals are subtracted, vertical scale is normalized per unit mass, spectra are vertically shifted for better presentation, differences in signal-to-noise ratios are due to variations in the weight of powders under study; (b) spin densities N_s of paramagnetic defects in PTB7 powders (yellow bars) and films (magenta bars).

reference sample, attached to the same substrate, were recorded in partially saturating ($P_{\text{MW}} = 5 \text{ mW}$) and over-modulated ($A_{\text{mod}} = 0.3 \text{ mT}$) conditions with receiver gain $= 2 \times 10^6$ and $n_{\text{aqc}} = 100$.

2.4 OPV fabrication and characterisation

Inverted OPV devices were initially prepared in a clean room environment using indium tin oxide (ITO) coated glass substrates ($R_s = 16 \text{ } \Omega$ per square, transparency = 84% purchased from Xinyan Ltd.) that were first cleaned using deionised water, acetone and isopropanol in an ultrasonic cleaner, then treated in a UV-ozone reactor with oxygen plasma for 10 minutes. A zinc oxide (Zn) electron transporting layer was prepared from zinc acetate dehydrate (109 mg) dissolved in 2-methoxyethanol (1 mL) and ethanolamine (0.03 mL) solution, which was spin-coated at 2000 rpm on the ITO substrate. The samples were then annealed in the presence of atmospheric air at temperatures of $150 \text{ }^\circ\text{C}$ for the Zn acetate to calcinate into ZnO. Active layer BHJ blends using PTB7 (as a donor) and [6,6]-phenyl- C_{71} -butyric acid methyl ester (C_{71} -PCBM) (as an acceptor) with weight ratios 1 : 1.5 were prepared and mixed with chlorobenzene solvent with a concentration of 30 mg mL^{-1} . Initial trials showed varying blend ratio and concentration for different PTB7 polymers led to the same optimal blend. Therefore, all results were obtained with PTB7 polymers which were prepared with the same ratio and concentration. To improve the performance and to be consistent with other reports, the processing additive 1,8-diiodooctane (DIO) was dissolved into the blend at a concentration of 2.5%.^{16–18} Prior to coating, the blend was allowed to dissolve for 1 hour on a hot plate at $45 \text{ }^\circ\text{C}$. Samples were transferred into a nitrogen atmosphere glovebox ($[\text{O}_2], < 1 \text{ ppm}$; $[\text{H}_2\text{O}], < 100 \text{ ppm}$), where the active layers was applied by spin-casting from a $45 \text{ }^\circ\text{C}$ solution. The active layer were annealed at $45 \text{ }^\circ\text{C}$ for 15 minute before thermal evaporation of the cathode was performed through a shadow mask to define device area and consisted of 8 nm of MoO_3 and 100 nm of silver (Ag).

Devices were checked for initial performance prior to lifetime testing. The measurement system used to characterize the devices consisted of a Newport solar simulator with 100 mW cm^{-2} AM1.5G output calibrated using a silicon reference cell from RERA in the Netherlands. The open circuit voltage (V_{oc}), short-circuit current density (J_{sc}), fill factor (FF) and PCE values are averaged from six cells (for each polymer). The devices were then placed under a halogen light source of 1 sun (calibrated by the silicon reference cell) for light soaking. Devices were kept at open circuit in between measurements and I - V measurements were made every 20 minutes, with more details of the procedure reported elsewhere.¹⁸ This was conducted in accordance with ISOS-L-2 standards.¹⁹ Devices were measured until the PCE reached 10% of its initial value.

3. Results

3.1 Material characterisation

PTB7 has been synthesized *via* Stille coupling reactions using two different palladium complex catalysts, $\text{Pd}_2(\text{dba})_2$ or

Scheme 1 Preparation of PTB7, in order from low (PTB7-1) to high molecular weight (PTB7-4).

$\text{Pd}(\text{PPh}_3)_4$, giving PTB7-1 and PTB7-3, respectively, as shown in Scheme 1. For a comparison, PTB7-2 and PTB7-4 were purchased from Lumtec Inc., Taiwan and Ossila Ltd., UK, respectively. The polymer notation is in ascending order of the molecular weight (PTB7-1 and PTB7-4 possess the lowest and the highest molecular weight, respectively). These values and the polymer polydispersity indexes (PDI) are summarized in Table 1 and Fig. S1 in the ESI.†

The absorption spectra of the PTB7 samples dissolved in THF and in thin film form are presented in Fig. S2† (see also Table 1). The absorption characteristics have some minor differences and this can be explained from the GPC data (see Fig. S1†). In particular, PTB7-3, has a small peak at the retention time around 18 min is seen, which corresponds to $M_n \approx 800\text{k}$. This indicates that a high molecular weight fraction is present and this is likely to contribute to form the shoulder absorption around 750 nm. In any case, the variation in optical performance of the polymers is not significant enough to cause large variations in solar cell performance. The optical band gap (E_g) was estimated from the onset of the absorption spectra in thin film. PTB7-3 shows the lowest λ_{max} and exhibits a broad absorption peak; therefore, it gives lower E_g of 1.57 eV than others ($E_g = 1.66$ – 1.67 eV). This is desirable from a photovoltaic point of view as it improves spectral match between the AM1.5G sunlight and the polymer absorption spectra. HOMO and LUMO levels were estimated from absorption and electrochemical measurements. For donor materials in OPV, deeper HOMO levels are preferred²⁰ and based on this assertion, PTB7-4 is likely to be the best candidate, however, the data indicate that only a moderate difference in solar cell performance should be observed between PTB7-1–4 samples.

3.2 EPR of powders and films

Fig. 1(a) shows dark EPR spectra of PTB7 powders of various molecular weights recorded at the same instrumental conditions (see Methods). EPR spectra of all powders demonstrate the same complicated polycrystalline pattern characterized by the effective g -factors $g_1 = 2.0064 \pm 0.0002$, $g_2 = 2.0048 \pm 0.0002$ and $g_3 = 2.00384 \pm 0.0002$. The similarity of g -factors between polymers indicates similarity of paramagnetic species revealed in all samples. At $P_{\text{MW}} > 1 \text{ mW}$ on both sides of the main signal, several broad satellite lines split by $\sim 0.4 \text{ mT}$ are observed. Signals of similar shape have been recently reported for

^a Errors in spin density determination do not exceed $\pm 15\%$. ^b Open circuit voltage. ^c Short-circuit current density. ^d Half lifetime of the OPV under 1 sun irradiation.

photothermally aged PTB7 films.¹¹ Simulation of this spectrum done using the model of a single $S = 1/2$ radical having tentative rhombically distorted structure where the uncoupled electron spin interacts with six $I = 1/2$ nuclei in surrounding, provides the following spin-Hamiltonian parameters: $g_1 = 2.0068$, $g_2 = 2.0038$, $g_3 = 2.0026$, and hyperfine proton couplings $a_1 = a_2 < 0.06 \text{ mT}$ and $a_3 = 0.36 \text{ mT}$ (see Fig. S4†).

Electron spin-lattice and spin-spin relaxation times were estimated from the saturation curves obtained for powder samples, and found to be the same (within $\pm 30\%$ estimation error) for all polymers under study: $T_{sl} = 1.4 \times 10^{-6} \text{ s}$ and $T_{ss} = 1.4 \times 10^{-8} \text{ s}$, respectively. This relatively short T_{sl} value found is similar to previous reports for undoped polymers that have been exposed to air at ambient temperature.²¹ EPR spectra of film samples being recorded under alternative instrumental conditions (see Methods) provide the same EPR patterns as their initial powders (spectra not shown).

Fig. 1(b) and Table 2 summarize densities of paramagnetic defects (positive polarons) in the samples, N_s , and evidence that in both powders and films the N_s density correlates inversely with the molecular weight: as lower is M_n as higher is N_s . Spin densities in polymers and films are found to be practically the same (within the experimental error) which indicates the film preparation and deposition do not create additional defects in polymer structures. This means that PTB7 samples do not incorporate spin-active units in their monomer structure and the observed radical defects present mostly on the polymer chain ends. Moreover, all results obtained on films correlated well with the OPV cell performance (see Table 2 and discussion below).

3.3 OPV performance

Fig. 2 shows the current density–voltage (J – V) characteristics of the BHJ OPV cells fabricated with **PTB7-1**, **-2**, **-3** and **-4** and C₇₁-PCBM. Averaged principle parameters of these cells are summarized in Table 2. It appears that the highest molecular weight polymer (**PTB7-4**) leads to the highest PCE of 6.71% whilst the lowest molecular weight polymer (**PTB7-1**) leads to the poorest OPV performance (PCE = 4.02%). The medium molecular weight polymer, *i.e.* **PTB7-2** and **PTB7-3** showed medium PCE of 4.92% and 6.04%, respectively. The observed

Fig. 2 J – V characteristics of OPV devices fabricated with polymers PTB7-1–4 under AM1.5G illumination.

Fig. 3 AFM images with indicated RMS values for PTB7:C₇₁-PCBM blends before (a, c, e, g) and after (b, d, f, h) light soaking. (a, b) PTB7-1:C₇₁-PCBM; (c, d) PTB7-2:C₇₁-PCBM; (e, f) PTB7-3:C₇₁-PCBM; (g, h) PTB7-4:C₇₁-PCBM.

improvement in PCE with the M_n increase is caused mostly by differences in J_{sc} . Since the absorption spectra of the samples are relatively similar, we explain this by two reasons. First, relationships between M_n , N_s and J_{sc} indicate that samples with higher M_n contain fewer recombination centers in the polymer moiety of the photoactive layer and thus exhibit higher photocurrents.

Second, this trend can also be equated to differences in the morphology of the photoactive layer. Lower M_n samples have smaller donor/acceptor interface area and thus provide poorer exciton dissociation efficiency. This statement is supported by AFM images of the photoactive layers (Fig. 3a, c, e and g). The highest molecular weight polymer *i.e.* **PTB7-4** (blended with C₇₁-PCBM) yielded the smoothest surface with Root Mean Square (RMS) roughness = 2.0 nm (Fig. 3(g)) whilst the low molecular weight one *i.e.* **PTB7-1** showed the highest: 7.2 nm (Fig. 3(a)). The **PTB7-2** and **PTB7-3** polymer with moderate M_n had an intermediate roughness of 5.9 nm and 4.9 nm, respectively. The discrete surface roughness is likely due to chain relaxation. Indeed, high molecular weight polymer, with high T_g , is difficult to move. Meanwhile, low molecular weight polymers, with lower T_g , are more mobile. Therefore they could relax from an as-spun ultra-smooth surface to a relatively rough surface during annealing and/or storage. Such relaxation could lead to undesirable phase separation²¹ and the increased film roughness could cause the decrease in the J_{sc} .²²

3.4 OPV performance

Lifetime stability tests for non-encapsulated devices were carried out under continuous illumination at 1 sun (Fig. 4). Overall, the device fabricated with the high molecular weight polymer (*i.e.* **PTB7-4**, M_n = 216k) possessed the highest stability, where the time to reach 50% of its initial value ($t_{1/2}$) was recorded at 96 hours. As the molecular weight of the polymer decreased, the stability of the devices appeared to reduce, as evidence by the fall in $t_{1/2}$ values. The decrease observed in PCE seems to be determined primarily by a drop in J_{sc} and supplemented by the decrease in FF.

Difference in morphological degradation in the active layer of the cells (Fig. 3) may be among the reasons for the variation

Fig. 4 Device characteristics for non-encapsulated PTB7-1-4:C₇₁-PCBM inverted solar cells as a function of time under illumination of 1 sun. Each parameter was normalised to the initial value at the start of the ageing process.

in J_{sc} degradation rates. Considering the topography before and after light soaking, it is clear that the most significant changes were observed for the lower molecular weight polymers. The RMS rose from 7.2 nm to 8.98 nm for **PTB7-1** (Fig. 3a and b) and from 5.9 nm to 7.8 nm for **PTB7-2** (Fig. 3c and d). At the same time, the **PTB7-3** and **PTB7-4** showed moderate increases of less than 0.5 nm (Fig. 3e-h). As discussed above, a drastic change of the photoactive layer morphology could lead to undesirable donor-acceptor interfaces and could be a reason for the rapid drop in J_{sc} in **PTB7-1** and **PTB7-2** during light soaking. It is clear from the AFM data that a morphological change occurred during ageing experiments, leading to potential phase segregation. At the same time, the density of recombination centers could increase. For the moment, it is difficult to distinguish which mechanism is more dominant and leading to the fall off in J_{sc} in Fig. 4.

On the other hand, the observed correlation between the cell PCE and lifetime suggests a general trend: the more efficient cells should be more stable. Indeed, photoinduced degradation of PV devices under operation is caused by sunlight. The more incident sunlight power converted to electrical power, the less remains for activation of degradation. During operation of polymer PVs, some fraction of the excitons generated under sunlight undergo non-radiative quenching leading to the photochemical degradation.¹¹ Efficient PV conversion due to the donor-acceptor charge transfer suppresses this process. Indeed, adding acceptor (PCBM) to the polymer blends was found to slow considerably the polymer photochemical degradation, presumably *via* sub nano-second quenching of the reactive excited state by forming a lower energy charge transfer complex.^{23,24} On the other hand, in small-molecule fullerene OPV cells, photochemical degradation of fullerenes was reported to occur by the same mechanism in both bi-layer and BHJ devices.²⁵ However, the process in the BHJ is slower due to more rapid exciton quenching by charge-transfer.

At the present stage of research, it is probably too early to formulate this conclusion as a general rule. However, it should be taken into account for future development of various novel PV technologies (including OPV, and perovskite-based cells) and checked in further research.

4. Conclusions

In summary, we produced a number of PTB7 samples with various molecular weights ($M_n \sim 40\text{--}220\text{k}$) and presented material characteristics and photovoltaic performance and lifetime of OPV devices fabricated with these samples. EPR spectroscopy revealed an inverse correlation between M_n and the densities of paramagnetic defects N_s in both powders and films of PTB7. This indicates that the observed radical defects present mostly on the polymer chain ends. Moreover, we demonstrated a gradual improvement in the PCE of PTB7:C₇₁-PCBM OPV cells with the increase of M_n of PTB7 due to increases in the cell short-circuit current, J_{sc} . We attributed this effect to the lower density of recombination centers and better photoactive layer morphology in the samples with higher M_n . Finally, the correlation between PCE and stability of the OPV cells was documented, showing improvement of the OPV lifetime by $\sim 300\%$ for high M_n samples.

The reported findings constitute a basis for further research that should include on one hand more detailed EPR study of encapsulated and non-encapsulated blend films in as produced state as well as after various doses of solar illumination, and on other hand analyses extended to other polymers.
