# Poly(2-vinylpyridine) brushes as a reaction chamber to fabricate spiky gold nanoparticles†

Wenqin Wang,<sup>a</sup> Hanzhi Zou,<sup>a</sup> Guoke Xing,<sup>a</sup> Mengying Shang<sup>a</sup> and Tao Chen<sup>b</sup>

Using polymer brushes to guide the growth of gold nanostructures is of great scientific and technological importance. We report a new strategy to tune the shape of gold nanoparticles (NPs) on poly(2-vinylpyridine) (P2VP) brushes through vapor deposition polymerization of pyrrole: P2VP brushes loaded with AuCl<sub>4</sub><sup>-</sup> ions were exposed to pyrrole vapor, one-step synthesized gold NPs and conducting polymer polypyrrole (PPy). The spiky gold NPs were obtained by controlling the thickness of P2VP brushes and reaction time, and a possible mechanism was proposed. The as-obtained spiky gold NPs could be used as substrates for surface-enhanced Raman scattering (SERS). They exhibited excellent Raman enhancement performance and the enhancement factor (EF) was in the range (4.0–6.2) × 10<sup>5</sup> when 4-aminothiophenol was used as a probe molecule.

## 1. Introduction

Fabrication of noble metal nanoparticles (NPs) using poly-electrolyte brushes with charged groups as matrices have garnered increasing scientific interest because the as-obtained hybrid materials exhibit unique mechanical, electrical or optical properties.<sup>1–7</sup> In spite of recent popularity, synthesis of the hierarchical noble metal nanostructures by polymer brushes is still a challenge in nanoscience due to the inherent nature of polymer brushes. In addition, traditionally the synthetic strategy involves loading the polymer brush with metal-ion precursors (such as Ag<sup>+</sup> and AuCl<sub>4</sub><sup>-</sup>) followed by their *in situ* reduction to metal NPs using NaBH<sub>4</sub>. NaBH<sub>4</sub> is a strong reductant and borohydride reduction is a very fast process requiring only a few seconds to reduce most of the metal-ion precursors adsorbed on polymer brushes to tiny metal NPs.<sup>4</sup> In this case, because the size of metal NPs is sufficiently small, polymer brushes give full play to their function: not only prevent those tiny metal NPs from aggregating and but also serve as a capping agent to limit their growth.<sup>3,7</sup> Although the as-obtained hybrid materials have exhibited potential applications in many surface-based technologies, in some specific applications, such as surface-enhanced Raman scattering (SERS), it would be highly desirable to obtain complex, hierarchical noble metal structures with sharp edges, tips, nanoscale junctions and high surface areas, which can provide “hot spots” for remarkable Raman signal enhancement.<sup>8–11</sup>

It is well known that one of the main influence factors for morphology of noble metal particles is kinetic controlling.<sup>12–14</sup> Previous reports have demonstrated that a small change of growth rates of individual metal crystal facets could result in drastic change in the morphology and size of resultant metal crystalline structure.<sup>13</sup> Therefore, to metal NPs/polymer brushes system, controlling the growth rate of noble metal NPs within polymer brushes and simultaneously hindering original function of polymer brushes (limiting NPs growth and their aggregation) would realize shape-controlled growth of noble metal NPs using polymer brushes as matrices. In this work, we attempted to use heterocyclic aromatic compound-pyrrole as reductant rather than NaBH<sub>4</sub> to reduce AuCl<sub>4</sub><sup>-</sup> ions adsorbed on poly(2-vinylpyridine) (P2VP) brushes. Because the standard reduction potential of the AuCl<sub>4</sub><sup>-</sup> is higher than the oxidation potential of pyrrole, pyrrole could be oxidized by AuCl<sub>4</sub><sup>-</sup> to conducting polymer-polypyrrole (PPy) and AuCl<sub>4</sub><sup>-</sup> be reduced to zero-valent gold simultaneously.<sup>15</sup> In above strategy, besides pyrrole as a relative weaker reducing agent lowered the growth rates of gold crystal, the presence of the formed PPy within polymer brushes could mitigate the polymer brushes’ disadvantage of limiting NPs growth, which would contribute to formation of gold NPs with complex morphology. Our strategy is schematically shown in Scheme 1: incubating P2VP brushes

Scheme 1 Schematic illustration of the fabrication of gold-PPy nanocomposites on P2VP brushes.

with  $\text{HAuCl}_4$  aqueous solution, the pyridyl groups, present along the polymer chains, were highly protonated and  $\text{AuCl}_4^-$  ions were bound tightly to the P2VP chains as counter ions of the protonated pyridine groups. When P2VP brushes loading  $\text{AuCl}_4^-$  ions were exposed to pyrrole vapors,  $\text{AuCl}_4^-$  ions acted both as an oxidant for pyrrole monomer and as a source of Au atoms, one-step yielding gold-PPy nanocomposites on P2VP brushes. By controlling the thickness of P2VP brushes and reaction times, gold nanostructures with different morphology were obtained.

## 2. Experimental section

### 2.1 Materials

2-Vinylpyridine, 3-aminopropyltriethoxysilane (APTES), and 4-aminothiophenol were purchased from Sigma. Pyrrole,  $\text{HAuCl}_4 \cdot 4\text{H}_2\text{O}$  (99.8%), toluene and  $\text{H}_2\text{O}_2$  (25%) were obtained from Sinopharm Chemical Reagent Co. (Shanghai, China). 2-Vinylpyridine was purified by neutral  $\text{Al}_2\text{O}_3$  column and pyrrole was distilled under reduced pressure before use. Other reagents were used as received without further purification. Highly polished single-crystal silicon wafers (N-doped, (100)-oriented silicon with a  $\text{SiO}_2$  layer thickness of 200 nm) were cleaned with “piranha” solution (**Caution:** Piranha solution reacts violently with organic matter) at 80 °C for 2 h, subsequently washed thoroughly with deionized water, and dried in a stream of  $\text{N}_2$ .

### 2.2 Surface-initiated polymerization by photografting and photopolymerization (SIPGP)

SIPGP technology according to previous reports:<sup>1,16,17</sup> A silicon wafer substrate which was treated with fresh “piranha” solution was immersed into a 5% APTES anhydrous toluene solution and sonicated for 30 min. Then, APTES molecules were attached as linker molecules *via* a silanization reaction. After thoroughly cleaned and dried by  $\text{N}_2$ , the APTES-functionalized silicon wafer substrate was submerged in bulk 2-vinylpyridine and irradiated for 3 or 5 h with an UV-light lamp with the spectral distribution between 300 and 400 nm ( $\lambda_{\text{max}} = 350$  nm) for the SIPGP. After the photopolymerization, the substrate was rigorously rinsed with different organic solvents in order to remove physisorbed polymer.

### 2.3 Preparation of gold-PPy composites on P2VP brushes

The P2VP brushes were incubated overnight in an aqueous solution of  $\text{HAuCl}_4$  (1 wt%). P2VP brushes loading  $\text{AuCl}_4^-$  ions were subsequently rinsed with deionized water and put into a reaction vessel (50 mL) equipped with a pyrrole solution loading reservoirs. The monomer in the reservoirs evaporated gradually and diffused into P2VP brushes loading  $\text{AuCl}_4^-$  ions, where the reaction was occurred. After reaction for a certain period (15 min, 30 min, and 1 h), the obtained products were rinsed with ethanol and dried in a vacuum oven at 50 °C.

### 2.4 Preparation of samples for surface-enhanced Raman scattering

The as-obtained gold NPs on silicon wafer were immersed into 4-aminothiophenol (4-ATP) ethanol solution with different concentrations for 3 h. Subsequently, the samples were rinsed with ethanol, and dried under nitrogen for SERS measurement.

### 2.5 Characterization

The morphology of the samples was observed by Scanning electron microscope (SEM, SU-70). X-ray photoelectron spectroscopy (XPS, Axis Ultra dld) was used to characterize chemical information of the products. Thermogravimetric analysis was determined with a PerkinElmer thermogravimetric analyzer (TG-DTA, SSC-5200) at a heating rate of 10 °C  $\text{min}^{-1}$  from room temperature up to 850 °C under air atmosphere. Raman spectra were recorded by using a microscopic confocal Raman spectrometer (Renishaw PLC) employing a 785 nm laser beam and acquisition time of 30 s.

## 3. Results and discussion

In our work, the P2VP brushes with different thickness (40 nm and 75 nm) were fabricated by SIPGP technology (the thickness of P2VP brushes was determined by atomic force microscopy (AFM), as shown in Fig. S1, ESI†). Grafting density of the obtained P2VP (75 nm thickness) was estimated to as 0.74 chains per  $\text{nm}^2$  by  $\sigma = 1/d_g^2$ , where  $d_g$  is the distance between two grafting sites, which was derived from  $d_g = M_n^{1/2}(N_A d \rho)^{-1/2}$ , where  $M_n$  (72 000  $\text{g mol}^{-1}$ ) is the number average molecular weight of polymer chains,  $N_A$  is the Avogadro's number, and  $\rho$  (1.18  $\text{g cm}^{-3}$ ) is the density of P2VP.<sup>18</sup> Because  $d_g$  was calculated as 1.16 nm, which is smaller than the radius of gyration of P2VP polymer coils ( $R_g \sim 5$  nm); so, the polymer layer can be considered as polymer brushes.<sup>19</sup>

Fig. 1 shows the growth of the gold-PPy nanostructures when P2VP brushes (40 nm thickness) loading  $\text{AuCl}_4^-$  ions were exposed to pyrrole vapor for different time (15 min, 30 min, and 1 h). In the initial stage (15 min), some gold nanoclusters are obtained (Fig. 1(A, a)). With reaction time prolongs to 30 min, flower-like gold nanoclusters are exhibited in Fig. 1(B, b). When reaction time increases up to 1 h, some raspberry-like gold nanostructures decorated on bumpy PPy layer are observed (Fig. 1(C, c)).

When P2VP brushes (75 nm thickness) loading  $\text{AuCl}_4^-$  ions were exposed to pyrrole vapors for different time (15 min, 30 min, and 1 h), the SEM images of the as-obtained gold-PPy composites are shown in Fig. 2. With reaction time prolongs, nanoclusters (Fig. 2(A, a)), spherical nanostructures (Fig. 2(B, b)), and spinous nanostructures (Fig. 2(C, c)) are observed, respectively. It is noted that the lower half of each spiky spherical NP is embedded into a thick PPy layer (Fig. 2c).

The actual formation mechanism is, as of now, unclear, a hypothesis is proposed. In our work, pyrrole is a relatively weaker reducing agent compared to  $\text{NaBH}_4$ . Pyrrole evaporates slowly to form vapor, which diffuses gradually to contact  $\text{AuCl}_4^-$  ions adsorbed on P2VP chains. Therefore, the reaction rate of

Fig. 1 Low- and high-magnification SEM images of the gold-PPy nanostructures when P2VP brushes (40 nm thickness) loading  $\text{AuCl}_4^-$  ions exposed to pyrrole vapors for (A, a) 15 min, (B, b) 30 min, and (C, c) 1 h.

pyrrole oxidized by  $\text{AuCl}_4^-$  ions is very slow. Initially, tiny gold nanocrystal and pyrrole oligomers are formed gradually along each P2VP chain. According to the report by Kim, sufficiently

Fig. 2 Low- and high-magnification SEM images of the gold-PPy composites when P2VP brushes (75 nm thickness) loading  $\text{AuCl}_4^-$  ions exposed to pyrrole vapors for (A, a) 15 min, (B, b) 30 min, and (C, c) 1 h.

small NPs can disperse freely within the polymer brushes.<sup>20</sup> Thus, in this case, those tiny gold nanocrystal and pyrrole oligomers can be immobilized within P2VP brushes. However, as the reaction continues, those gold nanocrystal and pyrrole oligomers grow increasingly into larger NPs, which are moved toward the polymer brush surface due to repulsive force imposed by the polymer chains.<sup>21</sup> When all P2VP chains are wrapped completely by the composites of gold nanocrystal and PPy, the P2VP chains can not work well for preventing aggregation, which results in gold-PPy composites layer on the surface P2VP brushes. In addition, it is also found that the final gold NPs existed on the surface of PPy layer instead of being embedded into PPy layer, which may be attributed to PPy growth in lateral directions (parallel to substrate) and gold NPs growth towards PPy-air interface. As to the significant morphology difference of gold NPs shown in Fig. 1 and 2, it could be interpreted that the amount of  $\text{AuCl}_4^-$  ions loaded by thicker P2VP brushes is more than that of thinner P2VP brushes, which provides sufficient source of gold for forming complex, hierarchical gold nanostructures.

To determine the surface composition, X-ray photoelectron spectrum (XPS) was employed to analyze the relevant samples. Fig. 3A shows the wide scan spectra of pure P2VP brushes and gold-PPy/P2VP composites. Compared with XPS spectrum of pure P2VP brushes, besides C 1s, N 1s and O 1s, Au 4f is observed. In high-resolution Au 4f XPS spectrum (Fig. 3B), the peak of Au 4f can be fitted into a main doublet peaks, and signals appeared at about 87.4 eV and 83.6 eV are assigned to Au 4f<sub>5/2</sub> and Au 4f<sub>7/2</sub>, respectively,<sup>3</sup> indicating the  $\text{AuCl}_4^-$  ions have been reduced to zero-valent gold ( $\text{Au}^0$ ). The N 1s high-resolution spectrum of pure P2VP brushes and gold-PPy/P2VP composites is shown in Fig. 2C and D, respectively. The N 1s peak at 399.3 eV is the characteristic peak of P2VP.<sup>22</sup> Compared with pure P2VP brushes, it is also found that the N 1s signal of gold-PPy/P2VP composites is slightly shifted to higher energy, which is indicative for the formation of PPy. The peak-fitted N 1s core-line spectrum of the gold-PPy/P2VP composites (Fig. 3D) shows that two nitrogen environments are present. The peaks at 399.9 eV is attributed to neutral nitrogen atoms ( $-\text{NH}-$ ) in PPy. The peak at 401.4 eV is assigned to positively charged nitrogen ( $-\text{N}^+-$ ) species in PPy.<sup>23</sup> The TGA of gold-PPy composites is shown in Fig. S2 (ESI<sup>†</sup>).

It is known that the dramatic Raman signal enhancement occurs on “hot spots”, which locate in the sharp corners and edges of noble metal nanostructures, or nanoscale junctions between two adjacent noble metal NPs.<sup>8–11</sup> Therefore, the spiky gold NPs (shown in Fig. 2C) is an ideal SERS substrate. Fig. 4 shows that SERS spectra of the spiky gold NPs using 4-ATP as the target analyte. Compared to the spectrum of the solid 4-ATP, the significant differences in the SERS of the gold NPs are the frequency shift for some bands and changes in the relative intensity. The  $\nu_{\text{CS}}$  band shifts from 1085 to 1079  $\text{cm}^{-1}$  and  $\nu_{\text{CC}}$  band shifts from 1594 to 1588  $\text{cm}^{-1}$ , indicating the  $-\text{SH}$  group in 4-ATP directly contacts the gold surface to form the Au-S bond.<sup>24,25</sup> To inquire quantitatively the enhancement effect of 4-ATP on spiky gold NPs, the surface enhancement factor (EF) value of 4-ATP on gold NPs is calculated according to the

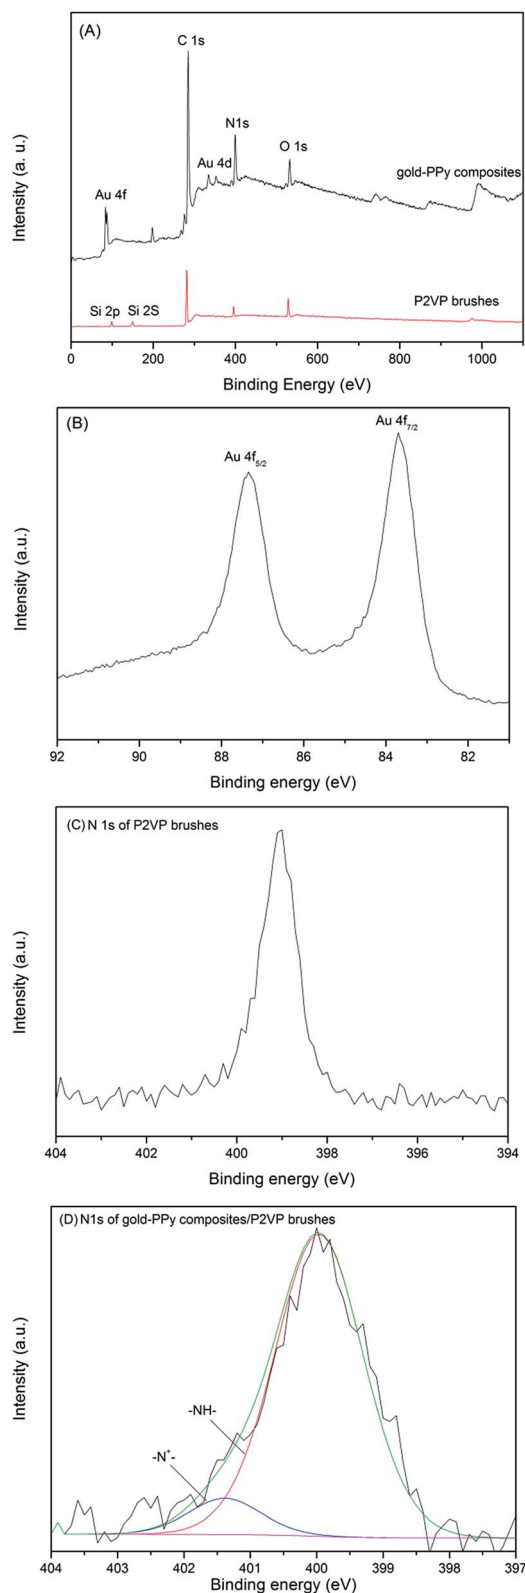

Fig. 3 (A) XPS of the pure P2VP brushes and gold-PPy composites/P2VP brushes, (B) Au 4f XPS spectrum of gold-PPy composites/P2VP brushes, (C) N 1s XPS spectrum of pure P2VP brushes, and (D) N 1s XPS spectrum of gold-PPy composites/P2VP brushes.

Fig. 4 Surface-enhanced Raman spectra of 4-ATP with different concentrations adsorbed on spiky gold NPs and Raman spectrum of solid 4-ATP.

following expression:  $EF = [I_{\text{SERS}}]/[I_{\text{Ref}}] \times [N_{\text{Ref}}]/[N_{\text{ads}}]$ ,<sup>26</sup> where  $I_{\text{SERS}}$  is the intensity of a vibrational mode in the SERS spectrum of 4-ATP and  $I_{\text{Ref}}$  is the intensity of the same mode in the Raman spectrum from the solid 4-ATP. For all spectra, the intensity of  $\nu_{\text{CS}}$  at  $1079 \text{ cm}^{-1}$  is used to calculate EF values.  $N_{\text{Ref}}$  and  $N_{\text{ads}}$  are the numbers of SERS molecules in the reference and sample within the laser spot. In our experiment, the focused laser beam with the laser spot ( $1 \mu\text{m}$  in diameter) and the penetration depth ( $2 \mu\text{m}$ ) is used.  $N_{\text{Ref}}$  is calculated assuming a cylindrical focal volume (the diameter of the laser spot is  $1 \mu\text{m}$  and the depth of the laser is  $2 \mu\text{m}$ ). Then,  $N_{\text{Ref}}$  of SERS molecules is calculated by  $N_{\text{av}}(\rho V_{\text{laser}}/M)$ , in which  $N_{\text{av}}$  is the Avogadro number,  $V_{\text{laser}}$  is the focal volume of the laser illumination,  $M$  is the molecular weight of 4-ATP molecule ( $125.19 \text{ g mol}^{-1}$ ), and  $\rho$  is the density of 4-ATP molecule ( $1.18 \text{ g cm}^{-3}$ ). So,  $N_{\text{Ref}}$  is  $8.91 \times 10^9$  per molecules. The number of the adsorbed molecules is poorly defined due to complex morphology of the gold NPs. In this work, we assume the all 4-ATP molecules are uniformly adsorbed on the gold NPs. This value can be obtained according to the method proposed by Orendorff *et al.*, which is  $N_{\text{ads}} = N_{\text{d}} \cdot A_{\text{laser}} \cdot A_{\text{N}} / \sigma$ .<sup>27</sup> Where  $N_{\text{d}}$  is the number density of the gold nanostructures,  $A_{\text{laser}}$  is the area of the focal spot of the laser and can be obtained from the diameter of the laser spot ( $1 \mu\text{m}$ ).  $A_{\text{N}}$  is the NP's footprint area assuming that the gold NPs are spheres with diameter about  $200 \text{ nm}$ .  $\sigma$  is the surface area occupied by an adsorbed 4-ATP molecule.  $N_{\text{d}}$  and  $A_{\text{N}}$  can be obtained from the SEM images in Fig. 2C. According to the report by Kim, each 4-ATP molecule occupies  $\sim 0.2 \text{ nm}^2$  on full coverage of Au, indicating that  $\sigma$  can be adopted as  $\sim 0.20 \text{ nm}^2$  per molecule.<sup>24</sup> So,  $N_{\text{ads}} = 2.46 \times 10^6$  per molecules. It is noticeable that the calculated error is ascribed to the  $N_{\text{d}}$  and the area of the gold NPs because they are approximately calculated according to the SEM images. According to the statistical results of the repeated SERS measurements, the ratio of  $I_{\text{SERS}}$  to  $I_{\text{Ref}}$  is  $(1.41 \pm 0.3) \times 10^2$ , so EF is calculated to be in the range  $(4.0\text{--}6.2) \times 10^5$ . This value is ranged with the highest EF values that have been

reported for 4-ATP molecules on gold nanostructures with other shapes.<sup>24–30</sup>

## 4. Conclusions

In summary, using P2VP brushes loading AuCl<sub>4</sub><sup>−</sup> ions as matrices and pyrrole as reductant, we have successfully demonstrated a new strategy to tune the morphology of gold nanostructures. Spiky gold NPs could act as potential SERS-active substrates for trace detection of organic molecules. This approach enriched the scientific research of polymer brushes and may be extended to produce many other types of noble metal-conducting polymer composites and open new pathways for engineering of noble metal nanostructures with unusual shapes.
