Introduction

The noninvasive measurement of temperature in vivo represents a growing area of research, largely due to its utility in medical applications such as low-temperature hyperthermia,^{1,2} high-temperature thermal ablation,^{1,2} and the treatment of heart arrhythmias.3 Here, thermometry may be used to discriminate normal from abnormal tissue, and also to ensure that thermal treatments are localized to prevent damage to healthy tissue.^{1,2,4} Magnetic resonance spectroscopy (MRS) and imaging (MRI) are particularly well-suited toward this end, owing to their use of non-ionizing radiation and ability to deeply penetrate tissue.^{1,5} Indeed, a number of temperaturesensitive MR parameters of water, including T_1 and T_2 relaxation times, proton resonance frequency (PRF), diffusion coefficient, and proton density, can be used to monitor tissue temperature.1,4,6 Currently, methods based on water PRF shift are the most widely used for imaging temperature in clinical studies due to their high-resolution and independence on tissue

Spin-crossover and high-spin iron(II) complexes as chemical shift ¹⁹F magnetic resonance thermometers†

Agnes E. Thorarinsdottir, Alexandra I. Gaudette and T. David Harris*

The potential utility of paramagnetic transition metal complexes as chemical shift ¹⁹F magnetic resonance (MR) thermometers is demonstrated. Further, spin-crossover Fe^{II} complexes are shown to provide much higher temperature sensitivity than do the high-spin analogues, owing to the variation of spin state with temperature in the former complexes. This approach is illustrated through a series of Fe^{II} complexes supported by symmetrically and asymmetrically substituted 1,4,7-triazacyclononane ligand scaffolds bearing 3-fluoro-2-picolyl derivatives as pendent groups (L_x). Variable-temperature magnetic susceptibility measurements, in conjunction with UV-vis and NMR data, show thermally-induced spin-crossover for [Fe(L₁)]²⁺ in H₂O, with $T_{1/2} = 52(1)$ °C. Conversely, [Fe(L₂)]²⁺ remains high-spin in the temperature range 4–61 °C. Variable-temperature ¹⁹F NMR spectra reveal the chemical shifts of the complexes to exhibit a linear temperature dependence, with the two peaks of the spin-crossover complex providing temperature sensitivity than that afforded by the high-spin analogue, and *ca.* 40-fold higher sensitivity than diamagnetic perfluorocarbon-based thermometers. Finally, these complexes exhibit excellent stability in a physiological environment, as evidenced by ¹⁹F NMR spectra collected in fetal bovine serum.

type.⁷ However, these techniques suffer from a low temperature sensitivity of *ca.* -0.01 ppm per °C, and their ability to accurately determine absolute temperature is limited.^{1,7,8}

In order to overcome sensitivity limitations, paramagnetic lanthanide⁹ and transition metal complexes¹⁰ that function as MRS probes have been developed for thermometry. These complexes feature paramagnetically shifted proton resonances, thus minimizing the interference from background signal in biological tissue. In particular, proton resonances of Tm³⁺, Tb³⁺, Dy³⁺ and Yb³⁺ complexes have been shown to exhibit temperature sensitivities of up to 1.8 ppm per °C,^{9q} and have been employed for temperature mapping *in vitro* and *in vivo.*⁹ Additionally, transition metal MRS probes have been shown to exhibit similar sensitivity¹⁰ and may alleviate toxicity concerns associated with lanthanides.¹¹

While paramagnetic MRS probes offer significant improvements in sensitivity over PRF thermometry, they are nevertheless limited to the inherent Curie temperature dependence of chemical shift in paramagnetic compounds.¹² Alternatively, one can employ a strategy of tuning a physical parameter that itself depends on temperature and governs chemical shift. Since both contact (through-bond) and dipolar (through-space) hyperfine shift scale as S(S + 1), where *S* represents the electronic spin state, variation of *S* as a function of temperature can result in dramatic changes in chemical shift.¹² As such, an ideal temperature-responsive chemical shift probe might feature a value of *S* that changes with temperature. Spin-crossover Fe^{II}

[†] Electronic supplementary information (ESI) available: Experimental details, additional crystallographic, magnetic, and spectroscopic data, and crystallographic information files (CIFs) for $1a \cdot 0.5$ CH₃CN, 1b, 2a, 2b, and 3a. CCDC 1505471–1505473, 1505534, and 1505863. For ESI and crystallographic data in CIF or other electronic format see DOI: 10.1039/c6sc04287b

complexes that undergo a thermally-induced electronic spin transition from a low-spin, S = 0 ground state to a high-spin, S = 2 excited state satisfy just such a criterion. Moreover, the ligand field in spin-crossover complexes can be chemically modulated to precisely tune the crossover temperature ($T_{1/2}$), defined as the temperature at which the low-spin and high-spin states are equally populated,¹³ to near 37 °C. Indeed, the utility of spin-crossover in MR thermometry has been demonstrated through T_2^* modulation in Fe^{II}-based nanoparticles¹⁴ and through paramagnetic chemical exchange saturation transfer (PARACEST) in molecular Fe^{II} complexes.¹⁵

While the vast majority of MRS thermometry probes exploit changes in the chemical shift of ¹H NMR resonances, the employment of ¹⁹F MR offers several key advantages. First, the ¹⁹F nucleus features a 100% natural abundance, a nuclear spin of $I = \frac{1}{2}$, and a gyromagnetic ratio and sensitivity close to that of ¹H.¹⁶ Moreover, the near absence of endogenous fluorine signals in the body, the large spectral window of ¹⁹F resonances, and the remarkable sensitivity of ¹⁹F chemical shift to the local environment, give rise to NMR spectra with minimal peak overlap.17 Indeed, it has been demonstrated that ¹⁹F chemical shifts of transition metal porphyrin complexes are highly sensitive to their solution electronic structure, in particular to oxidation state and spin state.18 In addition, lanthanide-based ¹⁹F chemical shift probes for monitoring pH have been reported.¹⁹ However, despite the potential of S as a tunable parameter to increase the temperature sensitivity of ¹⁹F MR chemical shift, to our knowledge no paramagnetic ¹⁹F MR thermometers have been reported. In fact, diamagnetic perfluorocarbons represent the only examples of ¹⁹F MR thermometry, but the application of these compounds is limited by the small temperature dependence of their ¹⁹F chemical shifts that affords a maximum sensitivity of only 0.012 ppm per °C.²⁰

Given the advantages of ¹⁹F over ¹H MR, in conjunction with the temperature sensitivity of ¹H MR chemical shifts of our previously reported spin-crossover Fe^{II} PARACEST probes¹⁵ and the high-spin Fe^{II} ¹H MR shift probes reported by Morrow and coworkers,¹⁰ we sought to develop fluorine-substituted spincrossover and high-spin Fe^{II} complexes for chemical shift ¹⁹F MR thermometry. Herein, we report a series of complexes that feature new symmetrically and asymmetrically-substituted 1,4,7-triazacyclononane (tacn) derivatives with fluorinated 2picolyl donors. The potential utility of spin-crossover and highspin Fe^{II} complexes as chemical shift ¹⁹F MR thermometers is demonstrated through detailed analysis of their temperaturedependent spectroscopic and magnetic properties. Furthermore, these compounds exhibit excellent stability in a physiological environment, as revealed by variable-temperature ¹⁹F NMR spectra recorded in fetal bovine serum (FBS). To our knowledge, this work provides the first examples of paramagnetic chemical shift ¹⁹F MR thermometers.

Results and discussion

Syntheses and structures

With the goal to prepare air- and water-stable complexes, tacnbased ligands bearing three pendent pyridyl groups offer an ideal platform, as these hexadentate scaffolds have been shown to afford highly-stable Fe^{II} complexes.^{10,21} In addition, the ligand field can be readily tuned to obtain spin-crossover complexes within a physiologically relevant temperature range by chemical modulation of the electronic and steric properties of the pyridyl donors.^{21e,22} Toward this end, we sought to synthesize related ligands that support Fe^{II} complexes in selected spin states through controlled introduction of methyl groups into the 6-position of the pyridyl groups, which serves to weaken the ligand field by virtue of steric crowding at the Fe^{II} center. In addition, in order to enable utilization of these compounds in ¹⁹F MRS thermometry, we installed fluorine substituents onto the 3-positions of the pyridyl groups.

The preparation of ligands L_x (x = 1-3; see Fig. 1) was carried out through a five-step synthesis involving stepwise addition of 2-picolyl derivatives to the tacn backbone via reductive amination of the corresponding 2-pyridinecarboxaldehydes with tacn precursors (see Experimental section and Scheme S1⁺). Through judicious selection of the aldehyde reagent in each step, this synthetic route enabled the preparation of both symmetric and asymmetric tri-functionalized tacn-based ligands, appended with one or two types of 2-picolyl donors. Metalation of the ligands with Fe^{II} and Zn^{II} was effected through reaction of equimolar amounts of L_x and the corresponding divalent metal ion in CH₃CN. Subsequent diffusion of Et₂O into a concentrated CH₃CN or CH₃OH/CH₃CN solution afforded crystalline $[Fe(L_1)][BF_4]_2 \cdot 0.5CH_3CN$ (1a $\cdot 0.5CH_3CN$), $[Zn(L_1)]$ - $[BF_4]_2$ (1b), $[Fe(L_2)][BF_4]_2$ (2a), $[Zn(L_2)][BF_4]_2$ (2b), and $[Fe(L_3)]$ - $[BF_4]_2$ (3a).

Single-crystal X-ray diffraction analysis for 1a · 0.5CH₃CN, 1b, 2a, 2b, and 3a, was carried out at 100 K (see Table S1⁺). Compound 1a · 0.5CH₃CN crystallized in the triclinic space group $P\overline{1}$, and features two $[Fe(L_1)]^{2+}$ cations in the asymmetric unit. Compound 1b crystallized in the monoclinic space group *Pc*, with the asymmetric unit comprised of two $[Zn(L_1)]^{2+}$ cations. In contrast to the metal complexes of asymmetric L_1 , compounds 2a and 2b are isostructural and crystallized in the cubic space group $F\overline{4}3c$, with one third of the $[M(L_2)]^{2+}$ (M = Fe,Zn) cation in the asymmetric unit. In these two structures, the M^{II} metal center resides on a site of crystallographic three-fold symmetry. Finally, the asymmetric unit of the crystal structure of 3a, which crystallized in the trigonal space group P3, features one-third of three unique $[Fe(L_3)]^{2+}$ cations, with the remainder of each complex related through a crystallographic three-fold axis (see Fig. S1[†]).

In the cationic complex of each compound, the M^{II} center resides in a distorted octahedral coordination environment, comprised of three facially bound tertiary amine nitrogen atoms from the tacn backbone and three picolyl nitrogen atoms (see Fig. 2). Examination of bond distances associated with the Fe^{II} cations reveals the spin state of these complexes in the solidstate at 100 K (see Table 1). The mean Fe-N bond distances for 1a.0.5CH₃CN and 3a fall in the ranges 1.974(2)-2.088(2) and 1.969(3)-1.999(3) Å, respectively, indicative of low-spin Fe^{II} .^{15,22,23} In **1a**·0.5CH₃CN, the Fe-N_{Me-pyr} bond lengths of 2.085(2) and 2.090(2) Å are significantly longer than the Fe–N_{F-pyr} bond distances of 1.970(2)–1.978(2) Å, due to the steric effects imposed by the methyl substituent on one of the picolyl groups.²² In contrast, the average Fe– $N_{MeF-pyr}$ and Fe– N_{tacn} bond distances for 2a of 2.224(2) and 2.230(2) Å, respectively, are substantially longer and are characteristic of high-spin Fe^{II}.^{22,23a-c,24} Finally, the mean Zn–N bond distances of 2.196(3) and 2.212(2) Å for 1b, and 2b, respectively, are consistent with reported distances for Zn^{II} ions in similar coordination environments.25

The presence of fluoro and methyl substituents on the 2-picolyl pendent groups of ligands L_{1-3} leads to a distortion from octahedral coordination at the metal centers. This deviation from perfect octahedral geometry can be quantified through the octahedral distortion parameter Σ , defined as the sum of the absolute deviations of the 12 cis-oriented N-M-N angles from 90°.²⁶ Analysis of the Fe^{II} centers in 1a · 0.5CH₃CN, 2a, and 3a gives values of $\Sigma = 72.4(3)$, 134.8(3), and 59.9(4)°, respectively. The much larger value for 2a than for 1a · 0.5CH₃CN and 3a reflects the significant steric crowding in 2a and further corroborates the high-spin and low-spin assignments of these complexes.²⁷ The larger distortion of the $[Fe(L_1)]^{2+}$ cation in $1a \cdot 0.5 CH_3 CN$ relative to $[Fe(L_3)]^{2+}$ in 3a is attributed to presence of one vs. zero picolyl methyl substituents, respectively. The coordination environment of the Fe^{II} complex in 2a and its isostructural Zn^{II} analogue in 2b are similar, where 2b is slightly less distorted than 2a, evident from a smaller Σ value of $127.7(2)^{\circ}$. In contrast, the difference between the structures of $1a \cdot 0.5 CH_3 CN$ and 1b is substantial. Upon moving from Fe to Zn, the mean $N_{\rm tacn}\text{-}M\text{-}N_{\rm tacn}$ angle decreases by 7.1%, from 85.07(6) to 79.1(2)°, and the mean trans $N_{\rm tacn}\text{-}M\text{-}N_{\rm pyr}$ angles decrease by 10.7 (N_{Me-pyr}), and 10.2% (N_{F-pyr}), respectively. Finally, a more than two-fold increase in Σ is observed for **1b** relative to $1a \cdot 0.5 CH_3 CN$. These differences reflect a much

greater degree of distortion at the Zn^{II} center in **1b** than at the Fe^{II} center in **1a** · 0.5CH₃CN, which likely stems from increased coordination flexibility at the d¹⁰ Zn^{II} ion due to lack of ligand field stabilization, and the larger six-coordinate ionic radius of Zn^{II} (0.88 Å) compared to low-spin Fe^{II} (0.75 Å).^{27a}

Compounds 1a.0.5CH₃CN, 1b, 2a, 2b, and 3a feature intramolecular M…F distances in the range 5.094(2)-5.277(2) Å. The shortest M…F distances are observed between the 3-fluoro-2picolyl pendent groups and the Fe^{II} centers in compounds $1a \cdot 0.5 CH_3 CN$ and 3a, with slightly longer M…F distances of 5.26-5.28 Å in compounds 1b, 2a, and 2b. The longer Zn…F distance in 1b, compared to the corresponding Fe…F distance in 1a.0.5CH₃CN, can be attributed to the longer Zn-N bond distances relative to Fe. In the case of compounds 2a and 2b, the presence of bulky 3-fluoro-6-methyl-2-picolyl groups increase the M…F distances relative to 1a.0.5CH₃CN and 3a. Importantly, the $M \cdots F$ distances of **1a** and **2a** are within the optimal range of 4.5–7.5 Å to balance the benefits of paramagnetic hyperfine shift with the decrease in sensitivity due to spectral broadening,^{19d,e} which demonstrates the potential of these complexes as candidates for ¹⁹F chemical shift MR probes.

UV-vis spectroscopy

To probe the solution electronic structures of the cationic complexes in 1a, 1b, 2a, 2b, and 3a, UV-vis absorption spectra were collected for crystalline samples in CH₃CN solution. The spectrum of 1a obtained at 25 °C exhibits an intense band at 264 nm ($\varepsilon = 10~700~M^{-1}~cm^{-1}$), in addition to a weaker broad band at 424 nm ($\varepsilon = 2800 \text{ M}^{-1} \text{ cm}^{-1}$) with a high-energy shoulder (see Fig. 3 and S2[†]). Based on literature precedent of Fe^{II} complexes in similar ligand environments, we assign these absorption bands as ligand-centered π - π^* and metal-ligand charge transfer (MLCT) transitions, respectively.^{22,28} The UV-vis spectrum of **2a** at 25 °C is dominated by the intense π - π * band (λ_{max}) = 273 nm, ε_{max} = 11 100 M⁻¹ cm⁻¹), and an additional broad feature of low intensity between 320 and 460 nm ($\lambda_{max} = 375$ nm) corresponds to a MLCT transition (see Fig. 3, lower, and S3[†]). The weak intensity and the small temperature dependence between -35 and 65 °C for the latter band ($\varepsilon_{max} = 1000 \ vs. \ 700$ M⁻¹ cm⁻¹, respectively) are characteristic of high-spin Fe^{II}.^{28c,29} Compound 3a is also relatively insensitive to temperature changes and at 25 °C displays a similar ligand-centered π - π^* transition at 261 nm, but with a more intense MLCT band at

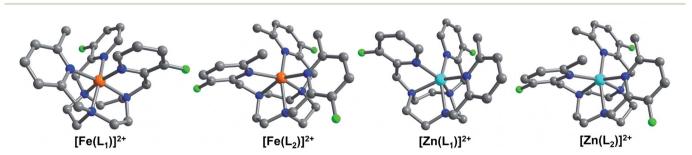

Fig. 2 (Left–Right) Crystal structures of $[Fe(L_x)]^{2+}$ (x = 1, 2), as observed in $1a \cdot 0.5$ CH₃CN and 2a, and $[Zn(L_x)]^{2+}$ (x = 1, 2), as observed in 1b and 2b. Turquoise, orange, green, blue and gray spheres represent Zn, Fe, F, N and C atoms, respectively; H atoms are omitted for clarity.

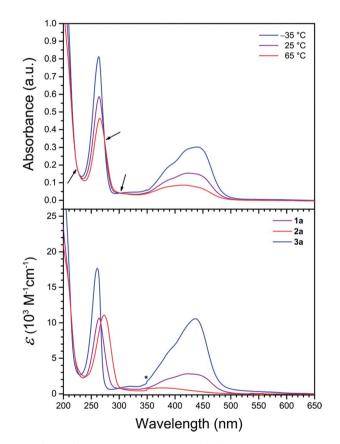

Fig. 3 (Upper) UV-vis spectra of 1a in CH_3CN at selected temperatures. Arrows denote isosbestic points. (Lower) UV-vis spectra in CH_3CN at 25 °C. The asterisk denotes an instrumental artifact.

436 nm ($\varepsilon_{\text{max}} = 10\ 600\ \text{M}^{-1}\ \text{cm}^{-1}$), and as such is indicative of low-spin Fe^{II} (see Fig. 3, lower, and S4[†]).^{22,30} The variable-temperature UV-vis spectra of the Zn^{II} compounds **1b** and **2b** in CH₃CN each exhibits a single intense band with $\lambda_{\text{max}} = 268$ and

278 nm, respectively (see Fig. S5 and S6†), consistent with ligand-centered $\pi-\pi^*$ transitions. 31

The absorption spectra of 1a demonstrate remarkable temperature dependence between -35 and 65 °C (see Fig. 3, upper). While the position of the π - π * band is relatively invariant to temperature, ε_{max} decreases significantly from 14 800 to 8400 M⁻¹ cm⁻¹ upon warming, as has been observed for related pyridyl complexes.32 At -35 °C, the MLCT band exhibits a λ_{max} value of 439 nm ($\varepsilon_{\text{max}} = 5500 \text{ M}^{-1} \text{ cm}^{-1}$) with a shoulder at ca. 385 nm. Upon warming, the MLCT bands broaden and decrease in intensity, resulting in a single peak with $\lambda_{\text{max}} = 385 \text{ nm} (\varepsilon_{\text{max}} = 1600 \text{ M}^{-1} \text{ cm}^{-1})$ at 65 °C that corresponds to ca. 3.5-fold reduction in intensity from the -35°C spectrum. This temperature dependence of the spectra is indicative of a thermally-induced spin state transition.^{22,33} Indeed, approximating a metal complex of $O_{\rm h}$ symmetry, the intensity of the MLCT band is directly correlated to the number of electrons in t_{2g} orbitals.^{32c,d} As such, moving from low-spin $Fe^{II}(t_{2g}^6)$ to high-spin $Fe^{II}(t_{2g}^4e_g^2)$ with increasing temperature results in a weaker absorption. Moreover, the presence of three isosbestic points at 222, 273, and 302 nm suggests an equilibrium between two spin states for the Fe^{II} centers in 1a.

The temperature-dependent spin state of Fe^{II} in **1a** in CH₃CN can be further examined by comparing the UV-vis spectra of **1a** with the corresponding spectra of the high-spin compound **2a** and the low-spin compound **3a** (see Fig. 3, lower). At lower temperature, the spectrum of **1a** strongly resembles that of **3a** (see Fig. S7†), whereas at higher temperature the broad spectrum resembles that of **2a** (see Fig. S8†). These temperature-dependent spectral changes demonstrate the thermally-induced spin-crossover of **1a** in CH₃CN solution from primary population of a low-spin state at -35 °C to a high-spin state at 65 °C.

With an eye toward employing these complexes in MR thermometry, UV-vis spectra were collected for aqueous solutions of compounds 1a, 1b, 2a, 2b, and 3a at ambient

temperature. All compounds show similar characteristics in H₂O as in CH₃CN, giving comparable values of λ_{max} and ε_{max} (see Fig. S9–S13^{\dagger}). Nevertheless, the spectrum of **1a** in H₂O reveals some key differences from the spectrum obtained in CH₃CN at 25 °C. The absorption maximum of the MLCT band is shifted to a longer wavelength in H₂O ($\lambda_{max} = 436$ nm), and the intensity of this band compared to the intensity of the analogous band for 3a in the same solvent is considerably greater in H₂O than in CH₃CN (H₂O: $\varepsilon_{max,3a}/\varepsilon_{max,1a} = 1.5$; CH₃CN: $\varepsilon_{max,3a}/\varepsilon_{max,3a}$ $\varepsilon_{\max,1a} = 3.8$). These observations indicate that moving from CH₃CN to H₂O serves to stabilize the low-spin state of $[Fe(L_1)]^{2+}$, leading to a higher $T_{1/2}$. Similar trends have been reported for other spin-crossover Fe^{II} complexes and stem from the donor strength of the two solvents.34 Importantly, 1a exhibits remarkable water and air stability, as the absorption spectra of this compound in deoxygenated water and after four weeks in oxygenated water are identical (see Fig. S9[†]).

Magnetic properties

To probe the magnetic properties of compounds 1a and 2a, variable-temperature magnetic susceptibility data were collected in the temperature range 5-60 °C for aqueous solutions in a 9.4 T NMR spectrometer using the Evans method (see Fig. 4).³⁵ For 2a, $\chi_{\rm M}T$ is constant over this temperature range, with an average value of $\chi_M T = 3.63 \text{ cm}^3 \text{ K mol}^{-1}$ that corresponds to a high-spin, S = 2 Fe^{II} ion with g = 2.20. In stark contrast, for 1a, $\chi_{\rm M}T$ increases nearly linearly with increasing temperature, from a minimum value of 0.93 cm³ K mol⁻¹ at 5 °C to a maximum value of 1.99 cm³ K mol⁻¹ at 60 °C, indicative of thermally-induced spin-crossover. Note that the high-spin excited state contributes considerably to the overall magnetic moment of **1a** at 5 °C, as the observed value of $\chi_M T = 0.93$ cm³ K mol⁻¹ is significantly higher than the theoretical value of 0 cm³ K mol⁻¹ for a solely populated S = 0 ground state. Analogously, a mixture of low-spin and high-spin Fe^{II} centers is present at 60 °C, as evident from the significant deviation of $\chi_M T = 1.99 \text{ cm}^3$

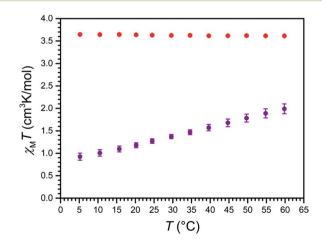

Fig. 4 Variable-temperature magnetic susceptibility data for aqueous solutions of **1a** (purple) and **2a** (red), obtained in a 9.4 T NMR spectrometer using the Evans method. Error bars represent standard deviations of the measurements.

K mol⁻¹ from the average value of the high-spin analogue **2a**. Considering a value of $\chi_{\rm M}T = 0$ cm³ K mol⁻¹ for a solely populated S = 0 low-spin state and $\chi_{\rm M}T = 3.63$ cm³ K mol⁻¹ for a solely populated S = 2 high-spin state with g = 2.20, the highspin molar fraction of Fe^{II} centers in **1a** was calculated as a function of temperature (see Fig. S14†). A linear fit to the data gives $T_{1/2} = 325(1)$ K or 52(1) °C. Moreover, the data were simulated using the regular solution model^{36,37} to estimate thermodynamic parameters of $\Delta H = 18.0(3)$ kJ mol⁻¹ and $\Delta S = 55.5(9)$ J K⁻¹ mol⁻¹, which are similar in magnitude to related mononuclear spin-crossover Fe^{II} complexes (see Fig. S15†).^{15,28c,36,38}

To test our hypothesis that the low-spin state of $[Fe(L_1)]^{2+}$ in **1a** is stabilized in H₂O relative to CH₃CN, variable-temperature magnetic susceptibility data were collected for an acetonitrile solution of **1a**, using the same procedure as described above (see Fig. S16†). As observed in aqueous solution, $\chi_M T$ increases nearly linearly with increasing temperature, from 0.62 cm³ K mol⁻¹ at -42 °C to 2.71 cm³ K mol⁻¹ at 60 °C. Furthermore, a linear fit to the data affords $T_{1/2} = 17(1)$ °C, which is 35 °C lower than observed in H₂O, and demonstrates the different donor strengths of the H₂O and CH₃CN (see Fig. S17†).

Variable-temperature NMR spectroscopy

To further investigate the solution properties of compounds 1a, **1b**, **2a**, **2b**, and **3a**, variable-temperature ¹H NMR spectra were collected in CD₃CN at selected temperatures. The ¹H NMR spectra of compounds 1b, 2b, and 3a resemble those of their respective ligands (see Fig. S18-S20[†]) and show minimal changes in the temperature range 25-56 °C, confirming diamagnetic electronic structures (see Fig. S21-S23[†]). In contrast, the ¹H NMR spectra of 2a display nine paramagnetically shifted resonances, consistent with time-averaged C_3 symmetry in CH₃CN solution (see Fig. S24[†]). At -1 °C, these resonances span -18 to 225 ppm, typical for high-spin Fe^{II} complexes.^{10,12,21b,d,e,g,h,28c} As the temperature is increased to 56 °C, the peaks shift linearly toward the diamagnetic region. This Curie behavior ($\delta \propto T^{-1}$) is characteristic of high-spin complexes and confirms that 2a remains S = 2 over the entire temperature range. In contrast, the ¹H NMR resonances of **1a** show anti-Curie behavior, shifting away from the diamagnetic region with increasing temperature (see Fig. S25[†]). Specifically, at -38 °C, the proton resonances are dispersed between -2 and 13 ppm, barely beyond the diamagnetic region, suggesting primary population of an S = 0 ground state. Increasing the temperature to 56 °C results in an expansion of the chemical shift range to -25-150 ppm, indicative of thermal population of the high-spin excited state. An analogous trend is observed in the variable-temperature ¹H NMR spectra of 1a in D₂O, though the resonances are broader and less shifted than in CD₃CN at analogous temperatures, giving a chemical shift range from -17 to 107 ppm at 56 °C (see Fig. S26[†]). These observations are consistent with the higher $T_{1/2}$ in H₂O relative to CH₃CN, as evident from solution magnetic measurements and UV-vis data.

In order to determine the effect of spin state on ¹⁹F resonances, and to assess these compounds as candidates for ¹⁹F MRS thermometry, we collected variable-temperature ¹⁹F NMR

spectra for aqueous solutions of **1a** and **2a** from 4 to 61 °C, using trifluoroethanol (TFE) as an internal standard (see Experimental section, Fig. S27, and Table S2†). To better understand how the temperature dependence of ¹⁹F NMR chemical shifts is affected by the electronic spin state, and to quantify the hyperfine shifts of the paramagnetic Fe^{II} compounds **1a** and **2a**, their corresponding Zn^{II} analogues, **1b** and **2b**, were employed as diamagnetic references (see Table 2).^{18c} Importantly, the chemical shifts of the fluorine resonances of Zn^{II} compounds **1b** and **2b** are effectively invariant to temperature changes (see Fig. 5, S28, and S29†).

At 4 °C, the ¹⁹F NMR spectrum of the high-spin compound 2a displays a single resonance at -59.4 ppm vs. CFCl₃ that is shifted +67.3 ppm from its diamagnetic Zn^{II} analogue 2b. As the temperature is raised to 61 °C, the chemical shift of the paramagnetic signal shifts upfield to -71.4 ppm, closer to the 19 F resonance of its diamagnetic analogue, as expected for Curie behavior (see Fig. S30 and S31, and Tables S3 and S4[†]). The observation of a single signal for 2a further supports the C_3 symmetry of the $[Fe(L_2)]^{2+}$ cation in solution, as suggested by ¹H NMR spectroscopy. Analysis of the temperature dependence of the ¹⁹F NMR chemical shift reveals a linear temperature dependence over 4–61 °C following the equation $\delta_{\rm ppm} = -0.21$ \times T - 58.8, affording a temperature coefficient³⁹ of CT = -0.21(1) ppm per °C (see Fig. 5, and Table 2). Since linewidth has a significant effect on the precision of MRS probes, the value |CT|/FWHM (FWHM = full width at half maximum) is also a useful measure of probe sensitivity. At 40 °C, the fluorine resonance of 2a exhibits a FWHM of 868 Hz, giving a |CT|/ FWHM = 0.11 per $^{\circ}$ C.

The ¹⁹F NMR spectrum of **1a** obtained at 4 °C exhibits two resonances of equal intensity at -99.3 and -102.1 ppm *vs*. CFCl₃ (see Fig. S32, and Table S3†), suggesting that the two 3fluoro-2-picolyl arms of L₁ are inequivalent on the NMR timescale. These peaks are shifted +23.1 and +20.3 ppm from the diamagnetic Zn^{II} analogue **1b** (see Fig. S33, and Table S4†), which exhibits two overlapping resonances centered at -122.3ppm (see Fig. S28†). Increasing the temperature to 61 °C results in a downfield shift of the resonances of **1a** to +51.3 and +44.8 ppm from **1b**, consistent with the anti-Curie behavior observed in the corresponding ¹H NMR spectra. The ¹⁹F chemical shift of both resonances for **1a** vary linearly between 4 and 61 °C following the equations $\delta_{ppm} = 0.52 \times T - 101.7$ and $\delta_{ppm} =$

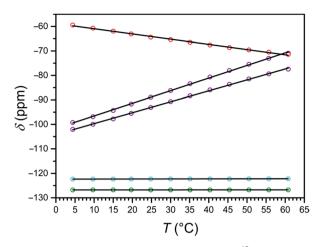

Fig. 5 Plot of the temperature dependence of the 19 F NMR chemical shift of 1a (purple), 1b (cyan), 2a (red), and 2b (green) in H₂O. Chemical shift values are corrected with TFE internal standard and referenced to CFCl₃. Solid black lines represent linear fits to the data.

 $0.45 \times T - 104.2$, providing temperature sensitivities of CT = +0.52(1) and +0.45(1) ppm per °C, respectively (see Fig. 5, and Table 2). Fluorine resonances with the narrowest linewidths are obtained at 20 °C, but the peaks broaden significantly above 55 °C (FWHM > 500 Hz). At 40 °C, the fluorine resonances each shows a value of |CT|/FWHM = 0.87 per °C.

The two ¹⁹F NMR resonances of **1a** exhibit 2.5- and 2.1-fold higher CT values than that of the high-spin **2a**. Furthermore, the narrower linewidths of the resonances of **1a** afford an 8-fold higher |CT|/FWHM value than **2a** at 40 °C. Remarkably, the two ¹⁹F resonances of **1a** represent 43- and 38-fold enhancement of temperature sensitivity compared to diamagnetic perfluorocarbons that have been employed for *in vivo* thermometry.²⁰ Despite the much narrower peak widths of the diamagnetic fluorine resonances relative to those of **1a**, the |CT|/FWHM value of **1a** at 40 °C is 2.9-fold higher owing to the strong temperature dependence of the chemical shift of its two resonances. These observations demonstrate that the use of spin-crossover complexes may provide an excellent strategy for improving the sensitivity of ¹⁹F MR thermometers.

Furthermore, the separation between the two fluorine resonances of 1a varies strongly with temperature, from 2.81 ppm at 4 °C to 6.52 ppm at 61 °C, following the linear relationship

Table 2 Summary of ¹⁹ F NMR properties for compounds 1a and 2a in CD ₃ CN, H ₂ O, and FBS solutions										
	CD ₃ CN		H ₂ O		FBS					
	1a		2a	1a		2a	1a		2a	
$\delta (\text{ppm})^a$ $\Delta \delta (\text{ppm})$	$59.4 +40.9^{b}$	52.6 +36.2 ^{b}	$55.9 \\ -13.6^{b}$	$41.6 +28.3^{c}$	$36.3 +24.6^{c}$	$59.2 - 12.0^{c}$	$40.7 + 28.8^{c}$	$35.5 + 25.1^{c}$	$59.0 -11.7^{c}$	
CT (ppm per °C)	$+0.67(2)^{b}$	$+0.59(2)^{b}$	$-0.24(2)^{b}$	$+0.52(1)^{c}$	$+0.45(1)^{c}$	$-0.21(1)^{c}$	$+0.52(1)^{c}$	$+0.45(1)^{c}$	$-0.21(1)^{c}$	
FWHM $(Hz)^d$	287	270	105	282	243	868	251	241	872	
CT/FWHM (per °C)	1.10	1.03	1.07	0.87	0.87	0.11	0.97	0.88	0.11	

^{*a*} Referenced to corresponding Zn^{II} analogues at 40 °C. ^{*b*} Obtained from the temperature range -22-40 °C. ^{*c*} Obtained from the temperature range 4–61 °C. ^{*d*} Obtained from data at 40 °C.

 $\Delta \delta_{\rm ppm} = 0.069 \times T + 2.47$ (see Fig. S34†). This peak separation provides an internal method of correcting errors in the ¹⁹F chemical shift that arise from complicating physiological effects, such as motion, magnetic susceptibility changes, and varying oxygen tension.²⁰ Overall, three temperature-dependent parameters of compound **1a** can be followed for MR thermometry, namely the ¹⁹F NMR chemical shifts of two inequivalent fluorine substituents, and the chemical shift difference between these signals.

To evaluate the efficacy of **1a** and **2a** in a physiological environment, ¹⁹F NMR spectra were collected from 4 to 61 °C on 13.4 and 15.0 mM solutions of **1a** and **2a**, respectively, in fetal bovine serum (FBS), using NaF as an internal standard (see Fig. S35†). The ¹⁹F NMR spectra in FBS are essentially identical to those recorded in H₂O and provide the same CT values (see Fig. S36 and S37 and Tables 2 and S5†). Plots of the temperature dependence of fluorine chemical shifts of compounds **1a** and **2a** in FBS are depicted in Fig. 6, where the chemical shifts of the Fe^{II} complexes have been referenced to the corresponding shifts

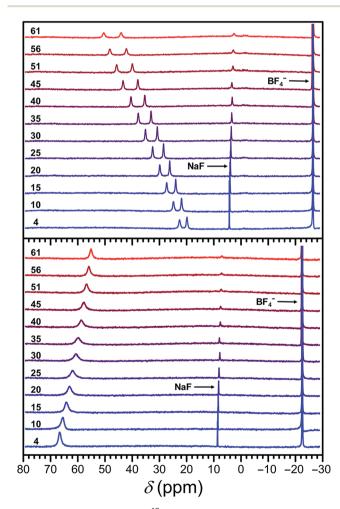

Fig. 6 Variable-temperature ¹⁹F NMR spectra of **1a** (upper) and **2a** (lower) in FBS, using a NaF internal standard. The chemical shifts of the Fe^{II} compounds **1a** and **2a** are referenced to their corresponding Zn^{II} analogues **1b** and **2b**, set to 0 ppm. Black numbers correspond to temperature in °C.

of Zn^{II} analogues **1b** and **2b** in water (see Table S6[†]). The linewidths for the resonance of 2a are similar in FBS and H₂O, while 1a exhibits slightly narrower peaks in the high-temperature region (>30 $^{\circ}$ C) in FBS compared to those in H₂O, resulting in higher |CT|/FWHM values in FBS. Furthermore, both complexes remain intact while incubated with FBS for over 24 h, as evidenced by identical ¹⁹F NMR spectra recorded at 25 °C initially and after 24 h (see Fig. S38 and S39[†]). Taken together, these results demonstrate the stability of compounds 1a and 2a in a physiological environment and indicate that temperature measurements with +0.52(1) and -0.21(1) ppm per °C sensitivity, respectively, can be achieved with these probes through chemical shift 19F MR thermometry. Moreover, the excellent stability and favorable ¹⁹F MR properties of 1a under physiological conditions suggest that this compound is a viable candidate for in vivo studies.

A comparison of the ¹⁹F NMR properties of compounds **1a** and **2a** in CD₃CN (see Fig. S40–S44†), H₂O and FBS is summarized in Table 2. The hyperfine shift of the spin-crossover compound **1a** is significantly affected by the solvent, in contrast to high-spin **2a** (see Tables S3 and S7†). Along these lines, the resonances of **1a** display a 1.3-fold higher temperature sensitivity in CD₃CN than in H₂O, which is consistent with a lower $T_{1/2}$ in CD₃CN. These observations reflect the pronounced effects of spin state on ¹⁹F NMR chemical shift, as has been previously reported for transition metal porphyrin complexes.¹⁸ Nevertheless, the results presented here provide a rare examination of spin state effects on ¹⁹F NMR spectra across a series of metal complexes.

Conclusions

The foregoing results demonstrate the potential utility of paramagnetic Fe^{II} complexes as chemical shift ¹⁹F MR thermometers. Most importantly, we show that the sensitivity of ¹⁹F MR thermometers can be improved by employing a temperature-dependent change in spin state, as illustrated in a series of Fe^{II} complexes. To our knowledge, these complexes represent the first examples of paramagnetic ¹⁹F MR chemical shift agents proposed for thermometry applications. Future efforts will focus on *in vitro* and *in vivo* MRS thermometry experiments on these compounds and the synthesis of spin-crossover complexes with higher sensitivity by exploiting the chemical tunability of the tacn-based ligand scaffold.
