A structurally-characterized peroxomanganese(IV) porphyrin from reversible O2 binding within a metal–organic framework†

Audrey T. Gallagher, Jung Yoon Lee, Venkatesan Kathiresan, ‡ John S. Anderson, ‡‡ Brian M. Hoffman ‡ and T. David Harris ‡‡*

The role of peroxometal species as reactive intermediates in myriad biological processes has motivated the synthesis and study of analogous molecular model complexes. Peroxomanganese(IV) porphyrin complexes are of particular interest, owing to their potential ability to form from reversible O2 binding, yet have been exceedingly difficult to isolate and characterize in molecular form. Alternatively, immobilization of metalloporphyrin sites within a metal–organic framework (MOF) can enable the study of interactions between low-coordinate metal centers and gaseous substrates, without interference from bimolecular reactions and axial ligation by solvent molecules. Here, we employ this approach to isolate the first rigorously four-coordinate manganese(IV) porphyrin complex and examine its reactivity with O2 using infrared spectroscopy, single-crystal X-ray diffraction, EPR spectroscopy, and O2 adsorption analysis. X-ray diffraction experiments reveal for the first time a peroxomanganese(IV) porphyrin species, which exhibits a side-on, η2 binding mode. Infrared and EPR spectroscopic data confirm the formulation of a peroxomanganese(IV) electronic structure, and show that O2 binding is reversible at ambient temperature, in contrast to what has been observed in molecular form. Finally, O2 gas adsorption measurements are employed to quantify the enthalpy of O2 binding as $h_{ads} = -49.6(8)$ kJ mol$^{-1}$. This enthalpy is considerably higher than in the corresponding Fe- and Co-based MOFs, and is found to increase with increasing reductive capacity of the $M^{II/III}$ redox couple.

Introduction

The activation of O2 by metalloproteins is central to a wide range of biological processes, including bond activation, O2 transport, metabolism, and the regulation of reactive oxygen species. In many of these processes, metal complexes of O2, or peroxide, represent reactive intermediates that are generated during the catalytic cycles of enzymatic reactions. For instance, C–H bond activation by heme-containing enzymes involves peroxyron intermediates. In addition, water oxidation by the oxygen-evolving complex in photosystem II and the degradation of superoxide ion by manganese superoxide dismutase are postulated to proceed through peroxomanganese intermediates. The prominence and unusual reactivity of peroxyiron and manganese species in biology has motivated efforts to synthesize and characterize synthetic molecular model complexes, largely in order to elucidate the structure, physical properties, and chemical reactivity of these intermediates. Indeed, tremendous progress has been made in the synthesis and study of both peroxoiron and manganese complexes. For instance, a number of mononuclear heme and non-heme peroxoiron complexes have been isolated, including two examples that have been structurally characterized. In addition, several mononuclear peroxomanganese species have been isolated, with two recent structurally-characterized examples featuring MnIV.

Despite these advances, significant challenges remain in the isolation of peroxomanganese complexes that display reversible O2 binding under ambient conditions, an important function often found in biological systems. Towards this end, manganese(IV) porphyrin complexes present an attractive platform, owing to their ability to carry out the two-electron reductive activation of O2 (ref. 11) and thus form high-valent peroxomanganese complexes. To date, one crystal structure of an O2 coordinated to a manganese porphyrin has been reported. This complex, formed by addition of KO2 to (TPP)MnIII (H2TPP = 5,10,15,20-tetraphenylporphyrin), was shown to feature a MnIII ion coordinated to a peroxy ligand in a side-on, η2 binding mode. While [(TPP)Mn(O2)]− provides an

important structural example of the peroxo binding mode, the presence of MnIII renders O2 loss unfavourable, as it would necessitate the formation of a high-energy MnIV species. In contrast, peroxomanganese(n) complexes, as formed by reaction of MnII with O2, have been probed by numerous spectroscopic techniques, including EPR,12a–c vibrational,12d NMR,12k and UV/visible12e spectroscopies, in addition to computational methods.12l–m Although these investigations support a side-on peroxomanganese(n) species has limited their characterization and hindered a thorough investigation of their structure and properties.

A key limitation in the study of O2 binding in molecular metalloporphyrins is the propensity for these species to form oxo-bridged complexes via irreversible bimolecular condensation reactions.11 For instance, in FeII and CoII complexes, highly elaborate ligands such as the sterically protected “picket-fence” porphyrins were necessary to prevent bimolecular decomposition reactions and enable the isolation and thorough characterization of six-coordinate Fe and Co–O2 adducts, which feature axial imidazole or thiolate ligands.14 In contrast, analogous axially-ligated MnIII complexes do not bind O2, which has been attributed to the preference for five-coordinate geometries in porphyrinic Mn ions.12a–d Consequently, no peroxomanganese(n) porphyrin species have been isolated or studied under ambient conditions.

As an alternative to employing molecular systems, one can envision isolating a peroxomanganese(n) complex within a porphyrinic metal–organic framework (MOF). Here, the porous, solid-state structure of the MOF prevents bimolecular condensation reactions and enables introduction of gas-phase substrates in the absence of exogenous solvent. Furthermore, whereas the inherent reactivity of the peroxomanganese(n) complexes has precluded crystallographic characterization, the crystallinity of MOFs provides an ideal platform to carry out single-crystal X-ray diffraction analysis. Illustrative of this approach, we have previously shown that the porphyrinic MOF PCN-224 (ref. 15) can be employed to study low-coordinate O2 adducts16,17 and labile carbonyl complexes.18 Herein, we comprehensively examine O2 binding to MnII in PCN-224 using a host of physical methods. Taken together, these experiments unambiguously establish the presence of a side-on peroxomanganese(n) species, and the O2 binding is shown to be reversible even at ambient temperature.

**Results and discussion**

**Synthesis of PCN-224MnII**

The porphyrinic MOF PCN-224 was synthesized as previously described.15 Subsequent metalation of the porphyrin with MnII was carried out by heating single crystals of PCN-224 under N2 in a DMF solution containing excess MnBr2 and 2,6-lutidine, followed by evacuation at 150 °C for 12 h, to give the compound PCN-224MnII (1). Complete metalation of the porphyrin within the bulk crystalline material was confirmed by solid-state diffuse reflectance UV/visible spectroscopy, trace metals analysis and powder X-ray diffraction (see Fig. 1 and S1 and Experimental section). Furthermore, N2 adsorption data collected for a desolvated sample of 1 at 77 K provided a Brunauer–Emmett–Teller surface area of 2455 m2 g−1 (see Fig. S2†), close to the accessible surface reported for other metalated variants of PCN-224,15–17,19 thereby confirming the retention of porosity upon metalation and the successful removal of solvent molecules from the pores. While several manganese porphyrin-containing MOFs have been reported, to our knowledge,19 1 represents the first example of a MOF that features a four-coordinate MnIII porphyrin complex.

The diffuse reflectance UV/visible spectrum obtained for an activated sample of 1 exhibits similar peak maxima to the absorption spectrum of 1 suspended in toluene, but nevertheless features key differences (see Fig. 1). Most notably, the spectrum reported for 1 in toluene displays a Soret band at 448 nm, while the spectrum for activated 1 features a Soret band at 417 nm. These differences can possibly be attributed to the rigorous four-coordinate nature of the Mn center in 1, compared to a slight distortion from local D4h symmetry at Mn in the toluene solution imposed by Mn–toluene interactions as has been observed for the molecular analogue, (TPP)Mn (see crystallography discussion below).14,16 More specifically, these changes may be attributed to the difference in mixing of metal- and porphyrin-based π orbitals in the two complexes, as changes in the degree of mixing are known to influence the resulting adsorption spectra of metalloporphyrin complexes.21 In the case of the rigorously in-plane Mn center, the maximal

For comparison, the absorption spectrum for a toluene suspension of 1 (blue) is shown, highlighting changes in the peak positions with and without toluene.
overlap of Mn d_{xy,yz} and porphyrin π* orbitals may account for the changes in the features in the electronic spectrum of 1.

Infrared spectroscopy

As an initial investigation into the interaction between MnII and O2, a desolvated sample of 1 was exposed to ca. 1 atm of dry O2 and monitored by diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS). The addition of O2 to 1 at 298 K was accompanied by the appearance of three new vibrations, situated at 801, 984, and 1017 cm⁻¹ (see Fig. 2), indicative of conversion to a Mn–O2 complex in the compound PCN-224MnO2 (2). The vibrations at 801 and 1017 cm⁻¹ have been previously attributed to a lowering of local symmetry from D_{4h} to C_{2v} at MnII upon O2 binding.12 This symmetry reduction occurs due to a displacement of Mn from the N4 plane of the porphyrin upon the addition of an axial ligand, in this case O2. Moreover, the feature at 984 cm⁻¹ is identical within error to the formerly assigned ν_{O–O} vibration from a mixture of the molecular complex (TPP)MnII and O2, as isolated in a frozen Ar matrix at 15 K.12 Remarkably, in contrast to molecular systems, where the deoxymanganese(II) complex was only partially regenerated after purging with N2 at −78 °C, similar purging here with dry Ar gas at 25 °C gave a spectrum identical to that obtained for 1 before adding O2 (see Fig. 2).12 This process of adding then removing O2 could be cycled at least three times, underscoring the ability of the solid-state MOF to enable reversible O2 binding (see Fig. S3†).

The ν_{O–O} vibration in 2 at 984 cm⁻¹ is considerably lower than those of ν_{O–O} = 1195 and 1278 cm⁻¹ previously observed for O2 adducts of (TPP)Fe and (TPPCo) at 15 K, which have been unambiguously assigned as superoxometal(III) species.23 This contrast suggests that O2 binding in PCN-224MnO2 involves a two-electron transfer from MnII to O2 to give a peroxomanganese(IV) species, rather than one-electron transfer to give a superoxomanganese(II) species.12a,c,e−n Here, the weaker O–O bond in 2 relative to superoxo complexes can be primarily attributed to a doubly occupied π* orbital of an O2⁻²⁻ ligand compared to singly occupied orbital of O2⁻⁻. Additionally, the ν_{O–O} = 984 cm⁻¹ in 2 is higher than those of ν_{O–O} = 806 cm⁻¹ and 898 cm⁻¹ previously reported for the peroxoiron(III) complex3a [(OEP)FeO2] and the peroxotitanium(IV) complex3b (OEP)TiO2 (H₂OEP = 2,3,7,8,12,13,17,18-octaethylporphyrin), which both feature side-on coordination of O2⁻²⁻. This difference may stem from increasing stabilization of the σ bond of O2⁻²⁻ with increasing effective nuclear charge moving from FeII to TiIV to MnIV. In addition, the concomitant increase in Lewis acidity across the series may serve to pull electron density out of the O2⁻⁻, thereby strengthening the O–O bond by alleviating electron–electron repulsion in O2⁻²⁻. While the foregoing comparison of data is consistent with the presence of a side-on O2⁻²⁻ in 2, analysis of infrared spectra alone cannot definitively confirm this assignment.

Single-crystal X-ray diffraction

The stability of the Mn–O2 adduct in 2 prompted us to investigate both 1 and 2 using single-crystal X-ray diffraction analysis. The structure of 1 exhibits a four-coordinate MnII center, residing in a square planar coordination environment on a crystallographic special position of mmm site symmetry (see Fig. 3, S3, and Table S1†). Importantly, no significant residual electron density was located in the difference Fourier map, confirming the absence of axial ligation at Mn. The Mn–N distance of 1.998(5) Å is notably shorter than those of 2.082(2)–2.085(2) Å previously reported for the toluene-solvated compound (TPP)Mn·2C₆H₆.12b,24 While this molecular compound features a pseudo four-coordinate MnIV center, weak contacts between Mn and a toluene molecule, with a closest Mn–C_{toluene} distance of 3.04 Å, lead to a 0.19 Å displacement of Mn from the N4 plane and thus slightly longer Mn–N bonds relative to 1. As such, to our knowledge, the structure of 1 provides the first example of a four-coordinate Mn porphyrin species. The isolation of a rigorously four-coordinate Mn center within a porphyrin ligand is remarkable given the relatively large ionic radius of MnIV, and thus its propensity to displace out of the N4 plane to form five-coordinate complexes.12b,25 Indeed, the complex in 1 demonstrates the utility of MOFs to enable isolation of reactive low-coordinate metal complexes.

Exposure of single crystals of 1 to ca. 1 atm of dry O2 at −78 °C resulted in an immediate color change from purple to black. Subsequent X-ray diffraction analysis at 100 K revealed the formation of 2. The structure of 2 is globally quite similar to that of 1, but with key differences in the Mn coordination environment (see Fig. 3, S3, and Table S2†). Most importantly, the structure features a Mn ion that is coordinated to O2 via a side-on, η¹ binding mode. In addition, the Mn ion is displaced from the N4 plane by 0.80(2) Å, slightly longer than the displacement of 0.7640(4) Å observed for the peroxomanganese(III) unit in a potassium cryptate salt of [(TPP)MnO2]⁻.7b Likewise, the Mn–N and Mn–O distances of 2.170(9) and 1.76(3) Å in 2 are slightly shorter than the analogous mean distances of 2.184(4) and 1.895(4) Å in [(TPP)MnO2]⁻. While these differences are consistent with the presence of a smaller
ionic radius for Mn⁹⁄₈ vs. Mn³⁄₂, they should be regarded with caution owing to the positional disorder and large thermal ellipsoids of O atoms in 2 (see Fig. S4†). Finally, this crystallographic disorder also precludes a reliable determination of the O–O distance in 2. Here, this distance was fixed to a target value of 1.40 ± 0.02 Å, based on other peroxometal complexes with similar values of rO–O.⁹,¹³,¹⁵ and subsequent refinement of the structure gave a distance of 1.39(2) Å.

In the structure of 2, the O₅ peroxo atoms are related through a crystallographic mirror plane. As such, the structure was modeled with an O₂ unit bound symmetrically with respect to Mn. However, we cannot exclude the possibility of some asymmetry based on the current structure. Indeed, several previously reported crystal structures of η²-bound peroxometal complexes feature asymmetric coordination of the peroxo ligand.⁹,¹⁰ Nevertheless, the structure of 2 shows that the O–O bond eclipses the pyrrole-based N atoms. This conformation contrasts the results from charge iterative extended Hückel (IEH) calculations on a peroxomanganese(IV) porphyrin complex, which suggested the presence of a staggered peroxo ligand to alleviate electrostatic repulsion.¹⁹ However, the eclipsed conformation observed for 2 is consistent with those determined crystallographically for the peroxometal porphyrin complexes (OEP)[TiO₂]²⁻ (TPP)Mo(O₂)₂²⁻ and [(TPP)MnO₂]⁻.⁷,²⁶

Despite the large standard deviations in the structure of 2, this analysis unambiguously reveals the presence of an O₂ adduct coordinated to Mn through a side-on, η² binding mode, with the O₂ eclipsing the N atoms of the porphyrin pyroles. Moreover, the complex in 2 represents a rare example of both a structurally characterized peroxometalloporphyrin²⁶,²³,²⁸ and a peroxomanganese(IV) complex.⁹ To our knowledge, 2 provides the first crystal structure of a peroxomanganese(IV) in a porphyrinoid ligand and a rare example of a peroxomanganese(IV) in any ligand environment.⁹,²⁷

**Electron paramagnetic resonance (EPR) spectroscopy**

To further probe the electronic structures of 1 and 2, as well as the reversibility of O₂ binding, continuous wave X-band EPR spectra were collected on samples at selected temperatures between 298 K and 4.2 K (Fig. 4 and 5; see Fig. S5† for full temperature range). The spectrum obtained at 77 K for a rigorously activated sample of 1 shows a sharp axial pattern, with observed g values of g⊥ = 6 and g∥ = 2 that are characteristic of an S = 5/2 Mn⁹⁄₈ ion with zero-field splitting parameters of D > hν, E/D = λ = 0 (see Fig. 4, upper). In addition, the low field portion features a well-resolved six-line hyperfine splitting by the I = 5/2⁵⁷Mn nucleus, with a hyperfine constant of A⊥⁵⁷Mn = 49 G (138 MHz).

Addition of toluene to a crystalline sample of 1 led to a broadening of the g∥ region of the spectrum and an increase in the hyperfine coupling (Fig. 4, middle). Accordingly, simulation of the spectrum with the program Easyspin²⁷ show that

![Fig. 3](image-url) Reaction of 1 with O₂ to form 2. Vertices of the green octahedra represent Zr atoms; purple, red, blue, and gray spheres represent Mn, O, N, and C atoms, respectively; H atoms are omitted for clarity. Selected interatomic distances (Å) for 1: Mn–N₄ 0.80(2), Mn–N 1.998(5); for 2: Mn–N₄ 0.80(2), Mn–O 1.760(9), Mn–N 2.170(9).

![Fig. 4](image-url) Experimental (black) and simulated (red) X-band EPR spectra of 1 at 77 K after activation (upper), in toluene (center), and in a mixture of toluene and pyridine (lower).
interaction of 1 with toluene lowers the four-fold symmetry of the MnII ion, as indicated by the introduction of a non-zero rhombicity of the zero-field splitting, \( \lambda \approx 0.027 \), along with an increase in hyperfine coupling to \( A_{\perp}^{Mn} \approx 57 \) G (160 MHz). Addition of a three-fold molar excess of pyridine in toluene to 1 (Fig. 4, lower) further lowers the symmetry, as indicated by a further increase in the rhombicity and the hyperfine coupling to \( \lambda \approx 0.041 \) and \( A_{\perp}^{Mn} \approx 78 \) G (219 MHz), respectively. It appears that pyridine binding introduces a rhombicity in the hyperfine interaction as well, although precisely reproducing the poorly-resolved spectrum is not illuminating. The progressive departure from four-fold symmetry is evident from increases in \( \lambda \) (see Table S3†). The change in the spectrum simply upon addition of toluene solvent strongly supports the four-coordinate nature of activated 1, and the transformation to a five-coordinate complex even upon addition of toluene solvent, not merely with the strongly-coordinating pyridine. The progressive increase in hyperfine coupling in these three samples reflects an increasing departure of the MnII from the N4 plane.

Dosing 1 with ca. 1 atm of dry O2 resulted in conversion to 2, which features a rhombic spectrum at \( \sim 7 \) K (see Fig. 5, lower). As has been analysed in detail for Mn(TPP)O2, O2 binding yields a complex formally described as a high-spin MnIV peroxo species, with the rhombicity of this EPR spectrum associated with orbital mixing on the MnIV. Following the analysis for Mn(TPP)O2, the spectrum represents an \( S = 3/2 \) spin state with axial zero-field parameter, \( D < 0 \) and \( |D| \) much greater than the microwave quantum (0.3 cm\(^{-1}\)). In this case the spectrum comprises the overlap of two spectra, arising from transitions within each of the two doublets created by the zero-field splitting of the \( S = 3/2 \) state, and the g-values of those spectra depend only on the rhombicity parameter, \( \lambda \). As with (TPP)MnO2, the spectrum in Fig. 4 corresponds well to the limit \( \lambda \rightarrow 1/3 \), where both doublets exhibits a g-tensor with g values of \( [5.4-5.5, 2, 1.45]^{12} \). The feature at \( g = 5.4 \) exhibits the overlap of two \( ^{55}\text{Mn} \) hyperfine sextet patterns, where \( A' = 54 \) G (154 MHz) for the lower doublet and \( A'' = 89 \) G (251 MHz) for the upper doublet (see Fig. 5 and Table S3†). Orbital mixing on MnIV causes the difference in the observed \( ^{55}\text{Mn} \) hyperfine splitting for the two doublets.\(^{12,28} \)

The ratio of signal intensities for the two doublets is determined by the Boltzmann populations of the two doublets at the measurement temperature, as determined by the energy difference between them, \( \Delta = 2[D^2 + 3E^2]^{1/2} = 2[D(1 + 3\lambda^2)]^{1/2} \). Taking into account the negative sign of \( D \), the simulated overlapping spectra and their relative intensities at \( T = 4.2 \) K are nicely reproduced using the measured hyperfine coupling and, \( D = -1.76 \) cm\(^{-1}\), \( \lambda = 1/3 \), with a corresponding zero-field energy separation of the two doublets, \( \Delta = 4.07 \) cm\(^{-1}\). These values of \( D, \Delta \) can be compared to \( D = -2.48 \) cm\(^{-1}\), \( \lambda \sim 1/3, \Delta = 5.82 \) cm\(^{-1}\) for Mn(TPP)O2.

As the temperature is increased from 4.2 K, the populations of the two doublets begin to equalize and the spectra broaden, likely in some part because of rotation of the O2 (see Fig. S5†). Finally, when 2 was purged with Ar at 298 K and evacuated for 12 h, a spectrum identical to that for 1 was obtained (see Fig. S6†). This observation corroborates the reversibility of O2 binding at Mn as revealed by DRIFTS analysis.

**O2 adsorption**

The reversibility of the O2 interaction enables quantitation of the O2 binding thermodynamics in PCN-224MnII through variable temperature O2 adsorption measurements. Toward this end, O2 uptake data were collected at selected temperatures between 233 and 298 K, as depicted in Fig. 6 and S7–S8. At 233 K, the O2 isotherm exhibits an initial steep uptake at low pressure. As the temperature is increased, the slope of this steep region decreases until the isotherm becomes closer to linear at 298 K. To quantify the strength of O2 binding, the isotherm data were fit to a dual-site Langmuir–Freundlich model (see Table S4†), and subsequent treatment of the variable-temperature data with the Clausius–Clapeyron equation revealed a differential enthalpy of adsorption of \( \Delta h_{ads} = -49.6(8) \) kJ mol\(^{-1}\) at low loading, followed by a gradual drop near 1 : 1 Mn : O2 to a plateau at \( \Delta h_{ads} = -9(2) \) kJ mol\(^{-1}\). We assign these values to O2 binding at the Mn center and physisorption to the remainder of the MOF surface, respectively.

The binding of O2 to MnII in PCN-224MnII is significantly stronger than the analogous values measured for O2 binding at the four-coordinate metal centers in PCN-224FeII and PCN-224CoII of \( -34(4) \) and \(-15.2(6) \) kJ mol\(^{-1}\), respectively.\(^{16,18} \) As previously discussed, the difference in binding enthalpy can
primarily be attributed to the difference in the redox couple at the metal center, which is associated with electron transfer upon the binding of O₂. In line with this relationship, the enthalpy of M–O₂ binding from Mn to Fe to Co in PCN-224MII decreases as E₁/₂ (V vs. SCE) of M⁰⁺ decreases, with the analogous molecular metalloporphyrins becoming less reducing (Mn: −0.230; Fe: −0.047; Co: +0.320). Note, however, that the binding enthalpy in Mn is further strengthened by the fact that O₂ binding involves a two-electron transfer from Mn to O₂.

Conclusions

The foregoing results demonstrate the ability of a MOF to enable the isolation and crystallographic characterization of a four-coordinate manganese porphyrin center and its corresponding O₂ adduct. A combined array of single-crystal X-ray diffraction, solid-state infrared, and EPR analysis collectively demonstrate the O₂ complex to comprise a peroxo ligand bound in a side-on, π2 mode to an S = 3/2 Mn⁴⁺ ion. In addition, these experiments reveal that O₂ binding is reversible, even at ambient temperature, in stark contrast to behaviour observed in molecular analogues. Finally, O₂ gas adsorption measurements quantify the enthalpy of O₂ binding as h_ads = −49.6(8) kJ mol⁻¹. This value is considerably higher than in the corresponding Fe and Co-based MOFs, and the strength of binding is found to increase with increasing reductive capacity of the M⁰⁺ redox couple. Work is underway to carry out and study the protonation, O–O bond cleavage, and O-atom transfer ability of the peroxo ligand, with emphasis on isolating and structurally characterizing the intermediates involved in these processes.
