Introduction

The ability of fluorine to modulate the pharmacological properties of biologically active molecules and to improve metabolic stability has spurred the development of an array of synthetic methods for both incorporation and modification of fluorinated motifs within complex molecular settings.1 Of interest are α-trifluoromethyl alkenes, for they are known peptide isosteres,2 are medicinally relevant moieties in pharmacologically active compounds,3 and are synthetic intermediates to other fluorinated species4 (Scheme 1). For instance, cyclopropanation yields trifluoromethyl-substituted cyclopropanes, which are established tert-butyl isosteres,3a and radical defluorinative alkylation gives 1,1-difluoroalkanes, which are proposed toke mimics.3a,b,c

Although several routes for preparing α-trifluoromethyl alkenes are reported, they are frequently lacking in functional group compatibility or ease of operation. Current approaches for the synthesis of this motif fall under three categories: (1) Wittig-type methylation of trifluoromethyl ketones (TFMKs) under strongly basic conditions;6 (2) Suzuki, Negishi, and Kumada cross-couplings that employ arylboron species and highly volatile bromo-3,3,3-trifluoroprop-1-ene;7 (3) Peterson-type olefination of TFMKs that utilizes a Grignard reaction in its synthetic sequence, thus limiting proton group tolerance.8

As part of a program to access functionalized fluorinated motifs, we became interested in efficient routes to α-trifluoromethyl alkenes that were both structurally complex and functionally diverse. Two complementary strategies were envisioned: (1) employment of cores with α-trifluoromethyl-β-silyl alcohols as “masked” trifluoromethyl alkenes, thus allowing molecular complexity to be installed without incurring undesired side reactions of the alkene; (2) utilization of a solid, bench-stable organotrifluoroborate reagent for rapid, late-stage introduction of the 3,3,3-trifluoro-1-propenyl motif (Scheme 2). This reagent eliminates the use of a volatile compound with limited bench-stability in favor of a crystalline, bench-stable solid that can be readily synthesized on a multigram scale and provides access to an umpolung bond disconnection. Additionally, the use of aryl bromides rather than arylboron species offers improvement on the availability and cost of starting materials.

Results and discussion

Functionalization of masked α-CF3 alkenes

α-Trifluoromethyl-β-silyl alcohols were reported recently by Leadbeater and co-workers as viable precursors to...
A. Diversification of α-trifluoromethyl-β-silyl alcohols

B. Cross-coupling via designed trifluoroborate

Scheme 2. α-Trifluoromethyl alkenes via two complementary approaches.

α-trifluoromethyl alkenes. The scope of this approach was hampered by the lengthy synthetic sequence used to prepare each example and the general intolerance of their approach toward Lewis or Brønsted acidic functional groups. However, α-trifluoromethyl-β-silyl alcohols were noted to be surprisingly stable despite the known propensity of tertiary β-silyl alcohols to undergo spontaneous elimination under both weakly acidic or basic conditions. The origin of this stability is likely derived from electronic deactivation and steric shielding by the α-trifluoromethyl group. We imagined that these α-trifluoromethyl-β-silyl alcohols could serve as masked CF₃ alkenes, which would enable rapid diversification to assemble species that would not only be incompatible with the original sequence, but also give rise to α-trifluoromethyl alkenes that would be otherwise challenging, if not impossible, to prepare. Indeed, we envisioned that we could further elaborate these structures by executing C₃⁻C₃ photoredox cross-coupling, Suzuki cross-coupling, Buchwald–Hartwig amination, and palladium-mediated borylation. After functionalization, the relatively mild nature of dehydrative elimination would furnish structurally complex α-trifluoromethyl alkenes. The amenability of α-trifluoromethyl-β-silyl alcohols toward Suzuki–Miyaura coupling was first investigated. Three regioisomeric, brominated cores were prepared and subjected to cross-coupling with aryl trifluoroborates. Good reactivity without concomitant olefination was observed. The para- and meta-substituted aryl bromides coupled in high yield with aryl- and heteroaryl trifluoroborates under relatively standard conditions (Table 1). Cross-coupling using potassium cyclopropyltrifluoroborate also proceeded well using standard conditions. The steric bulk of the α-trifluoromethyl-β-silyl moiety initially impeded coupling of the ortho-substituted aryl bromide core. Using high throughput experimentation (HTE), suitable conditions for ortho-coupling were quickly identified (see ESI† for details on HTE studies). Electron rich, sterically bulky phosphine ligands were the most efficacious, with 1,2,3,4,5-pentaphenyl-1'-(di-tert-butylphosphino) ferrocene (QPhos) proving optimal. Using these conditions, cross-coupling proceeded smoothly to afford the ortho-arylated structure 2d. These conditions could also be extended to a dioxolane core 2g.

Amination of these aryl bromides proceeded smoothly with both aniline and morpholine, providing the corresponding products 2h and 2i in high yield. The latter emphasizes the utility of these α-trifluoromethyl-β-silyl alcohols as masked

trifluoromethyl alkenes, given the propensity of trifluoromethyl alkenes to undergo defluorinative amination under basic conditions.16

Although numerous arylboron species are commercially available, there is a paucity when compared to commercially available aryl halides. One could envision borylating trifluoroalkenyl-substituted aryl bromides, but this approach is complicated by the facile defluorinative borylation of trifluoromethyl alkenes, resulting in 1,1-gem-difuoroalkenes.17 Consequently, we were interested in the borylation of these masked trifluoromethyl alkenes to generate arylboron species capable of serving as points for further diversification. Palladium-catalyzed borylation using either bis(pinacolato) diboron18 or bisboronic acid (BBA)19 occurred efficiently and in good yield to provide access to aryloboron ester 2j and aryliboronic ester 2k (Table 1). Notably, treatment of the intermediate boronic acid obtained from the BBA approach with excess KHF2 induced no observable Peterson elimination. This is a testament to the stability of the masking motif, given that both fluoride-induced and weakly Lewis acid-induced elimination pathways are known with β-silyl alcohols.20,21 Aryloboron species 2j and 2k were effective cross-coupling substrates, reacting in good yield with 5-bromoindole and 7-bromo-3-fluorquinoline to give the products 5i and 5m, respectively (Scheme 3).

Given the difficulty observed when attempting to prepare Csp2–Csp3 linkages using two-electron manifolds,21 Ni/photorodox dual catalytic processes were next examined. This approach is convenient for Csp2–Csp3 coupling within complex molecular systems because it can be executed under mild conditions and displays broad functional group tolerance.22,23 A key feature of these methods is the use of carbon-centered radicals to enable room temperature transmetalation. As such, certain moieties that are prone to radical chemistry will engage in off-cycle reactions. For example, trifluoromethyl alkenes are known to undergo facile radical defluorinative alkylation, likely precluding them from this form of catalysis.24–27 Indeed, we conducted competition experiments and found alkylation of the alkene to be competitive with Ni-catalyzed cross-coupling (see ESI† for experimental details).

Thus, this reaction class is ideal for demonstrating α-trifluoromethyl-β-silyl alcohols as masked trifluoromethyl alkenes. Dual catalytic cross-coupling was initially investigated using secondary organotrifluoroborates and these brominated, masked alkenes.22 Selection of the appropriate additive was crucial in achieving good reactivity. Carbonates and other basic additives, which are typically employed in Csp3–Csp3 couplings involving organotrifluoroborates, provided only partial conversion. Hypothesizing that the basic additive may deprotonate the relatively acidic α-trifluoromethyl alcohol present in the aryl bromide, we examined alternative additives to sequester the BF3 generated upon oxidative fragmentation of the organotrifluoroborate. KF was identified as the most effective additive, enabling the Csp2–Csp3 cross-coupled products to be obtained in good yield (Table 2[A]). Success here is again remarkable because: (1) BF3 can catalyze Peterson elimination28 and (2) KF can be used despite the high fluorophilicity of silicon. Other radical precursors could also be utilized. Alkyl bis(catecholato) silicates coupled in good yield with brominated, masked trifluoromethyl alkenes, although higher catalyst loadings were required to achieve complete conversion in a timely manner (Table 2[B]).29 Simple aryl masked trifluoromethyl alkenes, in addition to more complex meta-chloro (2r) and pyridyl (2s and 2t) examples, cross-coupled in good yield. Ni/photorodox thioarylation was also possible (2t).25

To demonstrate the full potential of this strategy for diversification, unmasking of the functionalized α-trifluoromethyl-β-silyl alcohols using trimethylsilyl trifluoro-methanesulfonate (TMSOTf) was explored. Although it proceeded smoothly for most substrates, a major challenge was conducting the Peterson elimination in the presence of Lewis basic sites. We found that elimination can be accomplished for some of the more
recalcitrant substrates if a super-stoichiometric amount (1.3 equiv.) of TMSOTf are employed (e.g., isoquinoline 3a [Table 3]). Alternatively, the addition of an equivalent of HCl to protonate the basic site (e.g., the nitrogen of 2a) enables successful elimination using sub-stoichiometric amounts (0.6 equiv.) of TMSOTf. Substrates containing less basic amines (3e, 3h, 3m) readily underwent elimination using catalytic amounts of TMSOTf, supporting the hypothesis of Lewis base-mediated deactivation of TMSOTf. Substrates containing ketone (3d, 3f, 3g), alkene (3p), strained rings (3e, 3n), alkyl ether (3r), morpholine (3l), and acid sensitive furan (3h) functional groups underwent elimination in moderate to good yields. Unfortunately, while unmasking of free indole substrate 2l was successful, undesired side reactions were observed on the indole moiety. Elimination proceeded smoothly in the presence of an N-Boc piperidine (3o), although reprotection of the free amine was required upon reaction completion. Unmasking of α-trifluoromethyl-β-silyl alcohol 2t required additional TMSOTf or increased reaction temperature, for additional details see the ESI. Using 1.3 equiv. TMSOTf. Using 6.0 equiv. TMSOTf.

Direct access to α-trifluoromethyl alkenes using potassium trifluoromethylvinyl trifluoroborate

Direct, one-step Suzuki cross-coupling of potassium trifluoromethylvinyl trifluoroborate 6 with a host of aryl and heteroaryl bromides was next pursued. Initial success was found when using Pd(OAc)$_2$ with PPh$_3$ as a ligand (Table 4). Several aryl- and heteroaryl bromides containing a wide variety of functional groups were successfully cross-coupled, including a pyrido[2,3-b]pyrazine (4a), indanone (4b), thiophene (4d), benzofuran (4e), and a caffeine derivative (4g). Other substrates required variation of the phosphine ligand for palladium to impart good reactivity. A survey of commercially available palladium pre-complexes was sufficient. Both a quinazolinone (4e) and a benzoopyrazine containing a free secondary amine (4h) were successfully cross-coupled using the PCy$_3$ Pd G4 pre-complex. Similarly, SPhos Pd G4 performed well in the cross-coupling with a bromobenzothiazole (4f). Two examples, a benzocycloheptaazopyridine (4k, a derivatized form of Claritin®) and a pyridylfuranone (4l), demonstrated the amenability of this reaction to complex, highly functionalized, drug-like structures.

This organotrifluoroborate reagent, 6, provided an opportunity to demonstrate the complementarity and orthogonality of these two distinct approaches (Scheme 4). As such, we executed a synthesis in which two trifluoromethyl alkenes were sequentially introduced and functionalized. Suzuki cross-coupling of potassium trifluoromethylvinyl trifluoroborate 6 with brominated, masked trifluoromethyl alkene 1g afforded α-trifluoromethyl styrene 5a in good yield. Radical defluorinative alkylation of the trifluoromethyl alkene using disopropylammonium bis(catecholato) (3-methoxypropyl) silicate provided gem-difluoroalkene 5b, which subsequently underwent alcohol elimination to reveal an aliphatic trifluoromethyl alkene 5c in good yield. Trifluoromethyl alkene 5c then proceeded through a second selective radical defluorinative alkylation using N-Boc-pyrrolidine trifluoroborate to afford differentiated gem-difluoroalkene 5d. Synthesis of such a structure by any other means would prove challenging, if not impossible, using state-of-the-art approaches.

**Conclusions**

In conclusion, two complementary approaches for the synthesis of highly functionalized trifluoromethyl alkenes have been realized. First, the viability of α-trifluoromethyl-β-silyl alcohols as masked trifluoromethyl alkenes was validated, enabling rapid diversification through several cross-coupling approaches. The elaborated products readily underwent elimination to generate their corresponding trifluoromethyl alkenes. Second, the one-step (trifluoromethyl)vinylation of functional group-rich aryl- and heteroaryl bromides was achieved using potassium trifluoromethylvinyl trifluoroborate. Taken together, these two complementary approaches provide the means to access an array of structurally diverse α-trifluoromethylated alkenes that can be further leveraged to produce novel, fluorinated species.
