Fe₂O₃ enhanced high-temperature arsenic resistance of CeO₂–La₂O₃/TiO₂ catalyst for selective catalytic reduction of NO_x with NH₃

 Na Wang,^a Changfei Ye,^a Huidong Xie,^{*b} Chang Yang,^c Jinhong Zhou^d and Chengmin Ge^e

High-temperature arsenic resistance catalysts of CeLa_{0.5}Fe_x/Ti ($x = 0, 0.1, 0.2, 0.3, 0.4, 0.5$) series were prepared and measured under a simulation condition of arsenic poisoning. The as-prepared catalysts were characterized by XRD, SEM, TEM, and XPS. The specific surface area and pore size of the catalysts were measured. At $x = 0.2$, the catalyst shows the best arsenic resistance and catalytic performance. The active temperature range of the CeLa_{0.5}Fe_{0.2}/Ti catalyst is 345–520 °C when the gas hourly space velocity is up to 225 000 mL g⁻¹ h⁻¹. Compared with commercial vanadium-based catalysts, CeLa_{0.5}Fe_{0.2}/Ti shows much better catalytic performance. The introduction of Fe will improve the dispersion of CeO₂ and increase the concentration of Ce³⁺ and unsaturated active oxygen on the surface. The NH₃-TPD and H₂-TPR results show that the CeLa_{0.5}Fe_{0.2}/Ti catalyst has more acidic sites and more excellent redox performance than CeLa_{0.5}Fe₀/Ti. The CeLa_{0.5}Fe_{0.2}/Ti catalyst might have application prospects in the field of selective catalytic reduction of NO_x with NH₃.

1. Introduction

Nitrogen oxides (NO_x) are some of the main pollutants in the atmosphere, which can do great harm to the ecological environment and human health, such as, acid rain, photochemical smog, ozone depletion, *etc.*¹ Selective catalytic reduction (SCR) of NO_x with ammonia is the most effective method to reduce NO_x in flue gas of stationary sources. Currently, the most widely used commercial SCR catalyst is V₂O₅–WO₃(MoO₃)/TiO₂.^{2,3} The vanadium-based catalyst has many advantages as well as some unavoidable problems, such as, strong biological toxicity of vanadium, narrow temperature window (300–400 °C), easy oxidation of SO₂ to SO₃, and low N₂ selectivity at high temperature.⁴ Recent reports have shown that CeO₂ is the most powerful substitute for V₂O₅ because of its non-toxicity, high reactivity, and excellent oxygen storage and release capabilities.^{5–7} However, the adaptability and anti-inactivation ability of

CeO₂ in a complicated flue gas environment is still an urgent problem to be solved. Heavy metal arsenic, often existing in the form of volatile As₂O₃ or As₂O₅ in high-temperature flue gas, is toxic to commercial SCR catalysts.⁸ Early reports show that the arsenic poisoning of commercial catalysts is due to the coverage of the active sites on the surface of the catalyst by inactive As₂O₅ and the diffusion of arsenic oxides into the pores of the catalyst, which causes the blocking of the micropores in the catalysts.^{9–11} The current widely accepted view is that chemical deactivation is the main reason, because arsenic of high oxidation state, As(v), can interact with the active site of vanadium to reduce the surface acid sites.^{12–14} In order to improve the arsenic resistance, commercial vanadium-based catalysts often need many additives, such as WO₃ and MoO₃. It has been found that MoO₃ has better resistance to arsenic poisoning than WO₃ because MoO₃ can further improve the dispersion of active sites of vanadium.¹⁵ Current literature on arsenic resistance mainly focuses on adding MoO₃ to commercial vanadium-based catalysts. However the highest NO conversion of these catalysts after arsenic poisoning is less than 80%.^{16,17} It is also effective in improving the arsenic resistance of CeO₂-based catalysts by adding WO₃/MoO₃.^{18–20} However the reported highest NO conversion of the CeO₂-based catalysts after arsenic poisoning is only 75%. So far, there is no report on the CeO₂-based catalyst by adding Fe₂O₃ as arsenic resistance catalyst. Recently, our research group has developed the CeO₂–La₂O₃/TiO₂ vanadium-free catalysts, which can be used at high temperature and are expected to replace commercial vanadium-based catalysts. Owing to its catalytic activity, sulfur resistance and porous properties, TiO₂ is an excellent catalytic carrier. La₂O₃ is a good auxiliary component for

active component of CeO₂ because of the formation of Ce–O–La bond on the surface of CeO₂, which increases the acidic sites of the catalyst and the adsorption of NH₃ and NO. Because Fe-based catalysts have good deNO_x performance^{21,22} as well as good adsorption of arsenic owing to the formation of strong Fe–O–As chemical bond in the removal of the arsenic in the water treatment,^{23–26} it is expected that Fe₂O₃ can be used as an arsenic resistance catalyst. In this paper, the Ce–La–Fe–Ti catalysts were obtained by an impregnation method, using anatase as the carrier and Ce–La–Fe oxides as the active component. The deNO_x activity of the as-prepared catalysts was measured. The as-prepared catalysts were characterized by XRD, SEM, TEM, and XPS. The reason for the arsenic resistance was discussed.

2. Experimental

2.1 Reagents and preparation

The Ce–La–Fe–Ti composite catalysts were prepared by an impregnation method. First, a certain volume of deionized

$$\text{N}_2 \text{ selectivity (\%)} = \frac{[\text{NO}]_{\text{in}} - [\text{NH}_3]_{\text{in}} - [\text{NO}_2]_{\text{out}} - 2[\text{N}_2\text{O}]_{\text{out}} - [\text{NO}]_{\text{out}} - [\text{NH}_3]_{\text{out}}}{[\text{NO}]_{\text{in}} + [\text{NH}_3]_{\text{in}} - [\text{NO}]_{\text{out}} - [\text{NH}_3]_{\text{out}}} \times 100\% \quad (2)$$

water was added to a stainless steel reactor and heated to 60 °C. Then ammonia (25–28 wt%) and citric acid (analytical purity) were added to adjust the pH to 3–4 with stirring. After that, anatase pigment (TiO₂, industrial grade), Ce(NO₃)₃·6H₂O (industrial grade), La(NO₃)₃·6H₂O (industrial grade), and (NH₄)₂Fe(SO₄)₂·6H₂O (analytical purity) were added according to the different weight ratios, CeLa_{0.5}Fe_x/Ti (*x* = 0, 0.1, 0.2, 0.3, 0.4, 0.5), where 0.5 and *x* are the weight ratios of La (calculated as La₂O₃) and Fe (calculated as Fe₂O₃) to Ce (calculated as CeO₂). In all the Ce–La–Fe–Ti composite catalysts, the weight ratio of Ce–La–Fe to Ti (calculated as TiO₂) is 3 : 7. The suspension was stirred continuously for 2–3 h and evaporated by vacuum distillation for 1 h. Then the mixture was cooled to room temperature, ripen for 2 hours, dried at 105 °C for 12 h, and calcined at 500 °C in a muffle furnace for 5 h. Finally, the samples were used for the SCR activity test. For comparison, commercial vanadium-based catalysts obtained from the market were also used.

2.2 Catalyst activity tests

First, 1 g as-prepared catalysts were ground in a planetary ball mill for 90 min and soaked in 25 mL 1 mg mL^{−1} arsenic standard solution (calculated as As₂O₃) for 3 h to simulate its arsenic poisoning. The water solvent was completely evaporated, thus the loading amount of As₂O₃ on the catalyst was calculated to be about 2.5 wt%. Then the catalyst was adhered to an industrial honeycomb-shaped cordierite cylinder with size of φ20 × L50. After drying at 105 °C, the loaded cylinder was calcined in a closed tube furnace at 450 °C for 3 h. Then the loaded cylinder was put into a quartz tube furnace to test

the activity of the catalyst. The loading amount of the catalyst is 0.8 g. The gas composition is 500 ppm NO, 500 ppm NH₃, 300 ppm SO₂, 3% O₂, 5% H₂O, and N₂ is used as the balance gas. The total gas flow is 3000 mL min^{−1}, hence the corresponding gas hourly space velocity (GHSV) is calculated to be 225 000 mL g^{−1} h^{−1}. The outlet gas concentrations of NO, NO₂, SO₂ were detected by the Germany Ecom flue gas analyzer and the N₂O concentration was detected by the KRM50 infrared flue gas analyzer. The temperature program was controlled by a computer. At each temperature, the experiment was kept for 30 min to stabilize before the data collection of the concentration of the outlet gas. The NO conversion and N₂ selectivity were calculated according to the formula (1) and (2).^{27,28}

$$\text{NO conversion (\%)} = \frac{[\text{NO}]_{\text{in}} - [\text{NO}]_{\text{out}}}{[\text{NO}]_{\text{in}}} \times 100\% \quad (1)$$

2.3 Characterization

The Brunauer–Emmet–Teller (BET) specific surface area and pore volume of the samples were measured on the Micromeritics ASAP 2020 instrument. The morphology was observed on the Zeiss MERLIN compact field emission scanning electron microscope (FE-SEM) and a JEOL JEM 2100 plus transmission electron microscope (TEM). The X-ray diffraction (XRD) was performed on the Rigaku Ultima IV instrument, with a tube voltage of 40 kV, a tube current of 40 mA, and Cu Kα radiation. X-ray photoelectron spectroscopy (XPS) was performed on the Thermo ESCALAB 250XI electronic energy spectrometer, with C1s binding energy (284.8 eV) for energy calibration, X-ray source voltage of 16 kV, current of 14.9 mA, beam diameter of 650 μm. The temperature programmed chemical adsorption/reduction (TPD/TPR) was performed on the AutoChem1 II 2920 instrument. For NH₃-TPD, the catalyst was pre-treated under argon atmosphere at 350 °C for 1 h, then cooled down to 50 °C and adsorbed NH₃ to saturation. After that the temperature was raised to 100 °C and the catalyst was purged with Ar gas to desorb the physically adsorbed NH₃. Finally the temperature was raised to 500 °C at a ramping rate of 10 °C min^{−1} and the outlet NH₃ concentration was detected by the thermal conductivity detector (TCD). For H₂-TPR, the catalyst was pre-treated under Ar atmosphere at 350 °C for 1 h to remove the adsorbed gas on the surface, then cooled to room temperature. Then the catalyst was reduced in 10% H₂/Ar atmosphere from room temperature to 800 °C at a ramping rate of 10 °C min^{−1}. The H₂ consumption was detected by TCD.

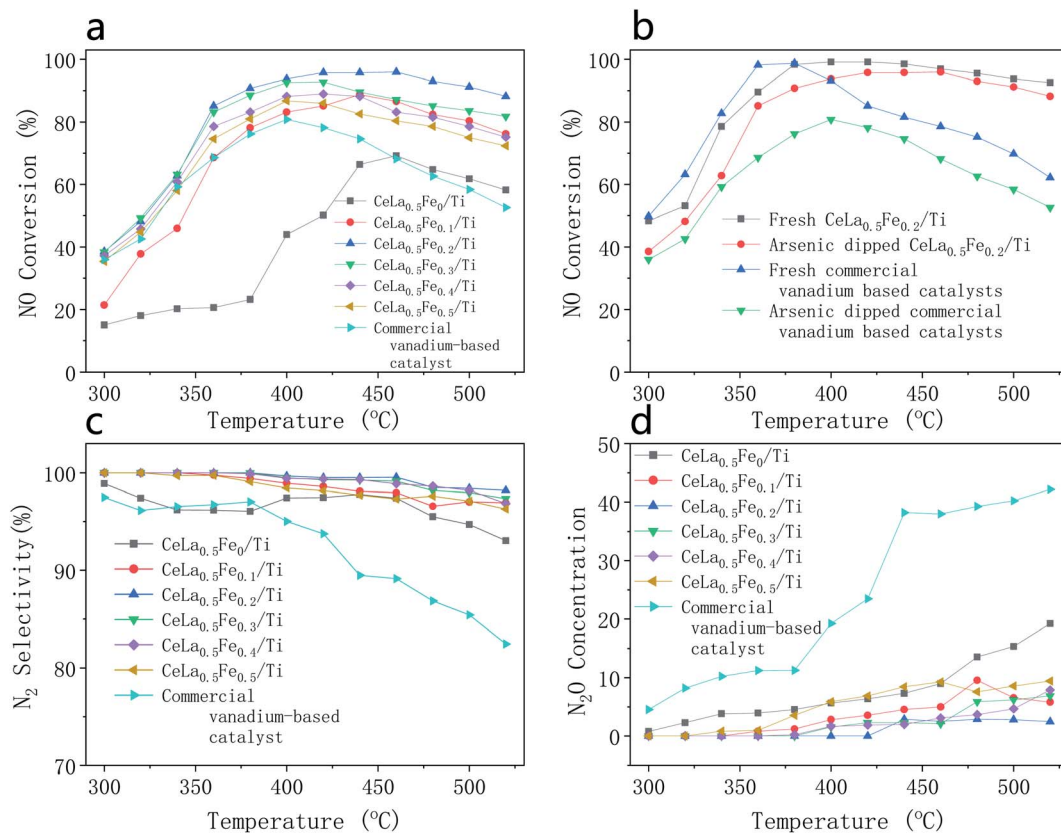

Fig. 1 Catalytic performance of catalysts with different components, all the catalysts were treated by arsenic as described in Section 2.2 except "Fresh" catalysts. (a) NO conversion of $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ ($x = 0, 0.1, 0.2, 0.3, 0.4, 0.5$) and commercial vanadium-based catalysts; (b) NO conversion of $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti}$ and commercial vanadium-based catalyst with and without arsenic solution dipping; (c) N_2 selectivity of $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ ($x = 0, 0.1, 0.2, 0.3, 0.4, 0.5$) and commercial vanadium-based catalyst; (d) N_2O concentration of $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ ($x = 0, 0.1, 0.2, 0.3, 0.4, 0.5$) and commercial vanadium-based catalyst.

3. Results and discussion

3.1 Catalytic performance

Fig. 1 shows the catalytic performance of catalysts with different components, in which all the catalysts were treated by arsenic as described in Section 2.2 except "Fresh" catalysts. It can be seen from Fig. 1(a) that the loading of Fe_2O_3 greatly improves the NO conversion. As temperature increases, the NO conversion first increases and then decreases. Influenced by the kinetics reason, the NO conversion will increase whereas the increasing trend will decrease with the increase of the temperature. If the temperature is too high ($>450^\circ\text{C}$ for $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti}$), the NO conversion will decrease due to the decrease of the N_2 selectivity. At the same temperature, the NO conversion first increases and then decreases with the increase of the Fe content. When the Fe_2O_3 content x is 0.2, the NO conversion of $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ is the highest. The temperature range where the corresponding NO conversion is greater than 80% of $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti}$ is $345\text{--}520^\circ\text{C}$. Commercial vanadium-based catalyst shows much weaker arsenic resistance than $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti}$. On the one hand, Fe-based catalysts have good deNO_x performance,^{4,5} on the other hand, Fe might form the bond of Fe-O-As^{6-9} with As, which makes Fe preferentially combine with As to protect the main active site of CeO_2 . However, excessive loading of Fe_2O_3 is detrimental to the deNO_x performance of the catalyst, which can be

attributed to the fact that excessive Fe_2O_3 will cover the active sites of the CeO_2 on the catalyst surface. Above 350°C , the NO conversion of the catalyst is maintained at a high level, which may be related to the enhanced oxidation of CeO_2 .²⁹ The introduction of La increases the surface unsaturated oxygen on the surface and the dispersibility of CeO_2 .^{30,31} From Fig. 1(b), it can be found that the commercial vanadium-based catalyst is significantly poisoned in arsenic environment, while $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti}$ catalyst is slightly affected in arsenic environment. The NO conversion of the $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti}$ is obviously better than commercial vanadium-based catalyst with regard to the arsenic resistance. In Fig. 1(c), the N_2 selectivity of the $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ ($x = 0, 0.1, 0.2, 0.3, 0.4, 0.5$) catalysts is much better than that of commercial vanadium-based catalyst and $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti}$ shows the best N_2 selectivity (99.08–100%). In Fig. 1(d), the N_2O concentration of vanadium-based catalysts increases quickly whereas the N_2O concentrations of $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ ($x = 0, 0.1, 0.2, 0.3, 0.4, 0.5$) increase slowly. This arsenic poisoning of vanadium-based catalysts is consistent with the results reported in the literature.⁴

3.2 XRD

Fig. 2 shows the XRD pattern of $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ ($x = 0, 0.1, 0.2$) series. The main phase of the three catalysts is anatase TiO_2 (JCPDS no. 99-0008). The broad diffraction peaks indicate that

Fig. 2 XRD pattern of $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ ($x = 0, 0.1, 0.2$) series.

the anatase is a nano-particle, which is consistent with the following SEM and TEM results. There are weaker cubic fluorite CeO_2 peaks (JCPDS no. 43-1002) near 28.6° , 33° , etc. The full width at half maximum (FWHM) of CeO_2 is wider than that of anatase, showing that the grain size of CeO_2 is much smaller than that of TiO_2 . However, there is no phase related to the

La_2O_3 , indicating that La_2O_3 is highly dispersed on the catalyst surface in an amorphous state, which is similar to the literature.³² The XRD peak of Fe_2O_3 ($\sim 33.15^\circ$, JCPDS no. 33-0664) is very weak and very wide, which indicates the Fe_2O_3 is amorphous. The FWHM of the (111) peak of the CeO_2 at 28.5° becomes wider with the increase of the Fe content, which means the addition of Fe decreases the CeO_2 grain size. Since CeO_2 is the main catalyst, small crystal size is beneficial to increase its catalytic activity. In addition, the peak of CeO_2 at 28.5° (after Gaussian fitting) moves towards higher angle direction, which might be caused by the formation of the solid solution of $\text{CeO}_2\text{-Fe}_2\text{O}_3$. This is because the radius of Ce^{4+} (eight-coordinated, 0.97 \AA) is larger than that of Fe^{3+} (eight-coordinated, 0.78 \AA). It is worth noting that although there are reports in the literature that anatase will transform into rutile at $\sim 500^\circ\text{C}$,³³ the rutile phase cannot be found in the catalysts, showing that the catalysts have good thermal stability.

3.3 SEM

Fig. 3 is the SEM images of the $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ ($x = 0, 0.1, 0.2$) series. According to the reports, the catalysts with the size of nano-particles can show high catalytic activity.³⁴ As can be seen, the active components are highly dispersed on the surface of the

Fig. 3 SEM images of $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ ($x = 0, 0.1, 0.2$) with different magnification. (a and b) $\text{CeLa}_{0.5}\text{Fe}_0/\text{Ti}$; (c and d) $\text{CeLa}_{0.5}\text{Fe}_{0.1}/\text{Ti}$; (e and f) $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti}$.

catalysts and the nano-particles form agglomerates with the size of sub-microns. The number of particles increases with the increase of the Fe content, which means that the addition of Fe may enhance the dispersion of CeO₂ on the surface of TiO₂. This is consistent with the XRD results.

3.4 TEM

Fig. 4 shows the TEM image, elemental mapping, and energy dispersive spectra (EDS) of CeLa_{0.5}Fe_{0.2}/Ti. The morphology in Fig. 4(a) clearly shows that the crystal size of the catalyst is tens of nanometers. In the HR-TEM image (Fig. 4(b)), the stripe spacing of 0.357 nm corresponds to the (101) plane of anatase TiO₂, and the stripe spacing about 0.318 nm corresponds to the (111) plane of CeO₂. The elemental mapping pictures of Ti, Ce, Fe, La, and O (Fig. 4(d-h)) show that the La, Ce, Fe and Ti elements are uniformly distributed in the catalysts. The EDS result in Fig. 4(i) shows that the main elements are Ti, La, Ce, Fe, and Cu, where Cu is caused by the Cu grid used to support the sample.

3.5 XPS

Fig. 5 is the XPS spectra of CeLa_{0.5}Fe_x/Ti ($x = 0, 0.1, 0.2$). The peaks of Ce, La, Ti, Fe and C can be found in the survey spectra

in Fig. 5(a). The Ce3d XPS spectra (Fig. 5(b)) can be fitted to nine peaks, named V₁ (≈ 880.7 eV), V₂ (≈ 882.3 eV), V₃ (≈ 885.8 eV), V₄ (≈ 888.6 eV), V₅ (≈ 898.3 eV), U₁ (≈ 900.8 eV), U₂ (≈ 903 eV), U₃ (≈ 907.3 eV), U₄ (≈ 916.7 eV). All V peaks correspond to Ce3d_{5/2} spin orbits, and all U peaks correspond to Ce3d_{3/2} spin orbits. The peaks of V₁, V₃, and U₂ correspond to Ce³⁺, while the peaks of V₂, V₄, V₅, U₁, U₃, and U₄ correspond to Ce⁴⁺.³⁵ From the peak area, the Ce³⁺ content on the CeO₂ surface increases significantly as the Fe content increases. Because of the different electrovalence of Fe³⁺ and Ce⁴⁺, in order to maintain charge balance, the oxygen vacancy defects on the CeO₂ surface also increase as the Fe content increases, which are beneficial to the improvement of the catalytic activity.³⁶ The XPS of O1s (Fig. 5(c)) can be fitted into two peaks: O_α (surface unsaturated oxygen, ≈ 530.6 eV) and O_β (lattice oxygen, ≈ 528.7 eV). Calculated by the fitted peak area, the O_α/(O_α + O_β) fractions of CeLa_{0.5}Fe₀Ti, CeLa_{0.5}Fe_{0.1}Ti, CeLa_{0.5}Fe_{0.2}/Ti catalysts are 43.30%, 43.73% and 43.78%, respectively. Because the surface unsaturated oxygen O_α of CeO₂ has a higher mobility and a stronger catalytic performance than the lattice oxygen O_β, CeLa_{0.5}Fe_{0.2}/Ti catalyst shows the best catalytic performance.³⁷ In Fig. 5(d), the peaks of Fe2p correspond to Fe2p_{1/2} (724 eV),

Fig. 4 TEM images, elemental mapping, and EDS of CeLa_{0.5}Fe_{0.2}/Ti. (a) TEM morphology, (b) HR-TEM, (c) all elements mapping, (d) Ti mapping, (e) Ce mapping, (f) Fe mapping, (g) La mapping, (h) O mapping. (i) EDS.

Fig. 5 XPS spectra of CeLa_{0.5}Fe_x/Ti ($x = 0, 0.1, 0.2$). (a) Survey spectra; (b) Ce3d; (c) O1s; (d) Fe2p.

Fe2p_{3/2} (711 eV) and satellite peaks. The peaks of Fe2p_{3/2} are fitted by two peaks of Fe²⁺ (710.0 eV) and Fe³⁺ (712.8 eV).³⁸ The CeLa_{0.5}Fe_{0.2}/Ti and CeLa_{0.5}Fe_{0.1}/Ti catalysts have no obvious differences in shape and positions, showing that the valences of Fe in the two samples are the same or similar. No obvious satellite peak and asymmetric peak are observed at ~715 eV, and the peak positions of 2p_{3/2}, satellite, and 2p_{1/2} are close to that of Fe³⁺. However the existence of Fe²⁺ must be considered because Fe²⁺ can be fitted in the curve. Therefore, it can be concluded that Fe³⁺ is the major valence while Fe²⁺ is the minor valence on the surface.³⁹

3.6 N₂ adsorption and desorption

The BET specific surface area, pore volume and pore diameter of CeLa_{0.5}Fe_x/Ti ($x = 0, 0.1, 0.2$) series were measured by N₂ adsorption and desorption experiments. The results were shown in Table 1. Because the main components of the catalysts are TiO₂, CeO₂ and La₂O₃, and the content of Fe₂O₃ is very little, the change of Fe content has little effect on the specific surface area of the catalyst. The specific surface area increases and the pore size increases slightly. The reason may be that the

introduction of Fe inhibits the growth rate of ceria grains and reduces the ceria grain size. This is consistent with the results of the XRD and SEM images.

3.7 NH₃-TPD and H₂-TPR

NH₃-TPD result reflects the acidity of the catalysts. Fig. 6(a) shows the NH₃-TPD curves of the CeLa_{0.5}Fe_x/Ti ($x = 0, 0.1, 0.2, 0.3$) catalysts. As can be seen, the CeLa_{0.5}Fe₀/Ti catalyst has two desorption peaks at about 350 °C and 290 °C. It is generally believed that the peak above 450 °C is related to the Lewis acid site (strong acid site) associated with the NH₃ molecule, and the peak near 300 °C is related to the Brønsted acid site (weak acid site) associated with NH₄⁺ ions.⁴⁰ From the peak area, the quantity of the Brønsted acid sites on the surface of the catalyst increases with the increase of Fe content up to $x = 0.2$, which helps to increase the catalytic activity. This is consistent with the catalytic performance in Fig. 1.

H₂-TPR result reflects the redox characteristics of the catalysts. Fig. 6(b) shows the H₂-TPR curves of the CeLa_{0.5}Fe_x/Ti ($x = 0, 0.1, 0.2, 0.3$) catalysts. The strong peaks of the four catalysts in the range of 450–580 °C correspond to the reduction process from Ce⁴⁺ to Ce³⁺, which are closely related to the catalytic activity of the catalysts.⁴¹ With the increase of Fe content x up to $x = 0.2$, the peak position shifts towards lower temperature direction from 577 °C to 473 °C, which means that the introduction of Fe makes the reduction of the surface oxygen on CeO₂ by H₂ more easy. However, when the Fe content increases to $x = 0.3$, the reduction peak changes from 473 °C to 515 °C, which means that the reduction of CeO₂ on the catalyst surface becomes more difficult. From the peak area, the H₂

Table 1 BET specific surface area, pore volume and pore diameter of CeLa_{0.5}Fe_x/Ti ($x = 0, 0.1, 0.2$) series

Catalyst	S_{BET} (m ² g ⁻¹)	V_p (cm ³ g ⁻¹)	D_p (nm)
CeLa _{0.5} Fe ₀ /Ti	78.1	0.040	3.25
CeLa _{0.5} Fe _{0.1} /Ti	79.7	0.039	3.28
CeLa _{0.5} Fe _{0.2} /Ti	79.9	0.041	3.32

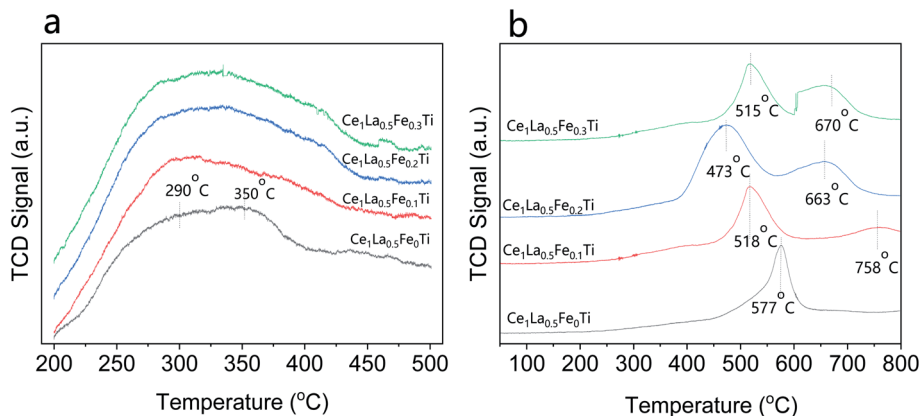

Fig. 6 (a) NH_3 -TPD curves of the $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ ($x = 0, 0.1, 0.2, 0.3$) catalysts; (b) H_2 -TPR curves of the $\text{CeLa}_{0.5}\text{Fe}_x/\text{Ti}$ ($x = 0, 0.1, 0.2, 0.3$) catalysts.

consumption is $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti} > \text{CeLa}_{0.5}\text{Fe}_{0.3}/\text{Ti} > \text{CeLa}_{0.5}\text{Fe}_{0.1}/\text{Ti} > \text{CeLa}_{0.5}\text{Fe}_0/\text{Ti}$, showing that the surface oxygen on CeO_2 increases with the increase of Fe content, which is consistent with the XPS results. Based on the NH_3 -TPD and H_2 -TPR curves, it can be concluded that $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti}$ catalyst has the most acidic sites and strongest redox performance.

4. Conclusions

An anti-arsenic SCR denitration catalyst with anatase as the carrier, CeO_2 , as the main active components, and La_2O_3 , Fe_2O_3 as the main auxiliary agent was prepared by the impregnation method. The optimized $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti}$ catalyst exhibits better catalytic performance under arsenic environment than the commercial vanadium-based catalysts. After the introduction of the Fe_2O_3 , the Ce^{3+} concentration, surface unsaturated oxygen, CeO_2 dispersibility, specific surface area, and acidic sites are all improved, which improves the catalytic activity in the arsenic environment. $\text{CeLa}_{0.5}\text{Fe}_{0.2}/\text{Ti}$ catalyst has high NO conversion efficiency, excellent N_2 selectivity and arsenic resistance, which might be a candidate for SCR denitrification applications in the arsenic flue gas environment.
