A QCM study of strong carbohydrate–carbohydrate interactions of glycopolymers carrying mannoses on substrates†

Takahiro Oh, Takeshi Uemura, Masanori Nagao,  Yu Hoshino  and
Yoshiko Miura *

Carbohydrates on cell surfaces are known to interact not only with lectins but also with other carbohydrates; the latter process is known as a carbohydrate–carbohydrate interaction. Such interactions are observed in complex oligosaccharides. It would be surprising if these interactions were observed in simple monosaccharides of mannose. In this study, the interaction between glycopolymers carrying monosaccharides of mannose was quantitatively investigated by quartz crystal microbalance measurements. We measured the interactions with glycopolymers carrying mannose, galactose and glucose. Surprisingly, the interaction between the glycopolymers and mannose was much stronger than that between other saccharides.

1. Introduction

Carbohydrates play important roles in various biological systems such as cell–cell adhesion, cell recognition, immune system, infection disease and cell differentiation.^{1–4} In glyco-science, most of the research focused on their specific interaction with carbohydrate–carbohydrate recognition proteins (lectins).^{5,6} Hakomori *et al.* found that carbohydrate–carbohydrate interactions (CCIs) are also present in living systems and play important roles in living systems.² However, the role of CCIs in biological systems is not completely clear, because CCIs have been studied less than carbohydrate–lectin interactions. CCIs have been reported to occur with a specific combination of oligosaccharides, such as Lewis X, G_{g3}, and G_{M3}. It is believed that CCIs are related to specific biological events such as cell recognition of cancer cells, and that CCIs are specific to the cells.^{2,7,8} If CCIs, which are expressed in complex oligosaccharides, are also present in monosaccharides, the implications for biology would be immense. But at the same time, CCIs have not been investigated for a wide variety of saccharides.

Mannose is frequently found in saccharides in living systems. For example, high mannose-type *N*-glycans function as a quality control system and enable intracellular transportation of glycoproteins.⁹ Mannose residues are abundant on the surfaces of pathogenic viruses and fungi and are intimately involved in pathogenicity and the host immune response in diseases.^{10–15}

Moreover, various immune cells, such as macrophages and dendritic cells, possess mannose-binding lectins, which play important roles related to immune response. Mannose is of high importance, and in particular, much attention has been given to the specific interaction of mannose with C-type lectins.^{16,17} It would be surprising if CCIs existed between simple mannose moieties.

The interactions of carbohydrates are usually weak, and the CCIs are even weaker than the carbohydrate–lectin interactions, which means they are difficult to measure.^{7,18} Glycoclusters, like glycolipids and glycoproteins, play important roles in exhibiting CCIs in the natural system. The artificial glycoclusters of glycopolymers are reported to amplify the carbohydrate interaction. It has been reported that glycopolymers can show CCIs based on the multivalent effect.^{19–21} Recently, we discovered a self-assembling mannose cluster comprising glyco-polymers in an aqueous solution, which suggested CCIs in glyco-polymers.²² In this report, we prepared a biomimetic interface with a glycopolymer-immobilized substrate to measure CCIs between simple mannose clusters (a mannose carrying glycopolymers); we measured this quantitatively and compared it with other simple sugar clusters.

2. Experimental section

2.1. Characterization

¹H NMR spectra were recorded with a JNM-ECZ400 spectrometer (JEOL, Tokyo, Japan) using CDCl₃, *d*₆-DMSO, or D₂O as a solvent. Gel permeation chromatography (GPC) with an organic solvent was performed using an HLC-8320 GPC Eco-SEC system

Department of Chemical Engineering, Kyushu University, 744 Motoooka, Nishiku, Fukuoka 819-0395, Japan. E-mail: miuray@chem-eng.kyushu-u.ac.jp

† Electronic supplementary information (ESI) available. See DOI: 10.1039/d1tb02344f

equipped with a TSKgel Super AW guard column and TSKgel Super AW (4000, 3000, and 2500) columns (Tosoh, Tokyo, Japan). GPC with water solvent was performed using a JASCO DG-980-50 degasser equipped with a JASCO PU-980 pump (JASCO Co., Tokyo, Japan), a Shodex OHpak SB-G guard column, a Shodex OHpak LB-806 HQ column (Showa Denko, Tokyo, Japan), and a JASCO RI-2031 Plus RI detector. GPC analyses were performed by injecting 20 μL of a polymer solution (1 g L^{-1}) in DMF buffer containing LiBr (10 mM) or NaNO_3 aqueous solution (100 mM). The buffer solution was also used as the eluent at a flow rate of 0.5 mL min^{-1} . GPC was calibrated using a poly(methyl methacrylate) standard (Shodex) for organic solvent GPC and pullulan standard (Shodex) for aqueous GPC. UV-spectra were recorded using an Agilent 8453 spectrometer (Agilent Technologies Inc., Santa Clara, CA, USA). Dynamic light scattering (DLS) was performed with a Zetasizer Nano-ZS (Malvern, UK). DLS analyses were performed by using a 1 mL disposable cell of a polymer solution (1 g L^{-1}) in HEPES buffer solution with Ca^{2+} (pH 7.4). A 27 MHz quartz crystal microbalance (QCM) system (Affnix Q8, Ulvac Inc., Japan) was used to monitor the interaction.

2.2. General procedure for polymer preparation

The glycopolymers were prepared by polymerization with a reversible addition fragmentation chain transfer (RAFT) reagent (Scheme 1).²² The polymers were prepared *via* the polymerization of 3-(trimethylsilyl)prop-2-yn-1-yl methacrylate (TMS-PrMA) with the RAFT reagent of CPADB and the polyethylene glycol (PEG) terminated chain transfer reagent. The saccharides of mannose (Man), galactose (Gal) and glucose (Glc) were added to the obtained polymer by the Huisgen reaction. The polymers prepared were homo-glycopolymers and polyethylene glycol (PEG) terminated glycopolymers. The polymer terminals were converted into thiol to immobilize the gold substrate. The details of the syntheses are described in the ESI.[†]

2.3. Glycopolymer immobilization on the QCM substrate

A 27 MHz QCM system was used to monitor the interaction. The QCM cell was cleaned with piranha solution (4 μL), and the solution was left for 10 mins and washed with Milli-Q

(three cycles). In the last cycle, the gold surface was replaced with Milli-Q 10 times. The QCM cell was placed in the QCM apparatus and monitored with 100 μL of Milli-Q until the frequency was constant. Once the frequency was constant, 100 μL of each glycopolymer was added to bring the concentration in the cell to 10 g L^{-1} , and the cell was kept at $15 \text{ }^\circ\text{C}$ for 2 hours. To remove unfixed glycopolymers from the cell, the cell was washed with Milli-Q three times, and then washed again with HEPES buffer and monitored until the frequency became constant.

2.4. Interaction measurement by QCM

A 27 MHz QCM system was used to monitor the interaction. The glycopolymers were immobilized on the QCM substrate as described in the previous section. After the frequency became constant, each PEG-terminated glycopolymer or PEG solution was added successively at $15 \text{ }^\circ\text{C}$, and the cell was measured until the frequency became constant.

2.5. Turbidity measurement

Each glycopolymer was dissolved in HEPES buffer (HEPES: 10 mM, NaCl: 137 mM, KCl: 2.7 mM, CaCl_2 : 1.8 mM) at 1 g L^{-1} . After incubation at $15 \text{ }^\circ\text{C}$ for 48 h, the absorbance of 600 nm was recorded.

2.6. X-ray photoelectron spectroscopy (XPS) measurement

XPS measurement was performed using a Shimadzu/Kratos AXIS-ultra (Kratos Analytical Ltd, Manchester, UK, Shimadzu Co., Kyoto, Japan) for the analysis of the immobilized glycopolymer. All the XPS spectra energies were referenced to the C (1s) photoemission peak at 285.0 eV. The substrates for XPS measurements were prepared by incubating the aqueous solution (10 g L^{-1}) of glycopolymers for 2 h on the glass substrate coated Au (50 nm).

3. Results and discussion

Fig. 1(a) illustrates the method of measuring the interaction between glycopolymers by quartz crystal microbalance (QCM) measurements, the chemical structures and the abbreviations of the polymers used in this investigation (Fig. 1(b)). **pGal₂₀₀**, **pMan₂₀₀**, and **pGlc₂₀₀** stand for glycopolymer carrying galactose, mannose, and glucose with the degree of polymerization (D. P.) of 200, respectively. **P₉₀Gal₂₀₀**, **P₉₀Man₂₀₀**, and **P₉₀Glc₂₀₀** stand for PEG-terminated glycopolymers. Glycopolymers were synthesized *via* reversible addition fragmentation chain transfer (RAFT) polymerization (TMS200) and the Huisgen reaction. PEG-terminated block glycopolymers were prepared by macro-RAFT with PEG (Fig. S4–4 and S4–6, ESI[†]). After the deprotection of the side chain of the TMS group (Fig. S4–5 and S4–7, ESI[†]), sugar azides (Fig. S4–1 and S4–3, ESI[†]) were incorporated into the polymer main chain by the Huisgen reaction (**pMan₂₀₀**, **pGal₂₀₀**, **pGlc₂₀₀**, **P₉₀Man₂₀₀**, **P₉₀Gal₂₀₀**, and **P₉₀Glc₂₀₀**).²² All the alkyne groups on the side chain were converted into sugar triazoles, which were confirmed by ¹HNMR (Fig. S4–8 and S4–9,

Scheme 1 Preparation of glycopolymers in this study *via* RAFT polymerization and the Huisgen reaction.

Fig. 1 (a) Schematic illustration of QCM measurement; (b) structures and abbreviations of glycopolymers and DHBG used in this study.

ESI[†]). The polymer terminals were converted into thiol by the deprotection of the TMS group, which was confirmed by the decrease of UV absorbance at 305 nm (Fig. S6–1, ESI[†]). Molecular weights were estimated by GPC measurements (S5-1 and S5-2, ESI[†]).

A glycopolymer thin layer with pGal_{200} , pMan_{200} , and pGlc_{200} was formed by the incubation of the gold electrode of QCM, and the substrate was rinsed with MilliQ water to remove the non-specific adsorbed polymer. The formation of the glycopolymer layer was monitored by QCM and X-ray photoelectron spectroscopy (XPS) (Fig. 2 and Fig. S7-1, S8-1, S8-2, S8-3, ESI[†]).²³ The time course of the frequency change in QCM indicated the adsorption of glycopolymers on Au-S, where the adsorption behaviour was different depending on the type of the polymer (Fig. 2 and Fig. S7-1, ESI[†]). The XPS spectra were recorded after the formation of the polymer layer and the rinsing with water. In the XPS spectra, the decrease of Au (4f) and the strength of C (1s) peaks showed the formation of the glycopolymer layer

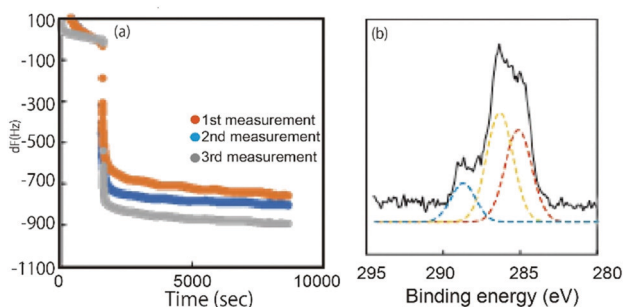

Fig. 2 Glycopolymer layer formation by adsorption of thiol-terminated pMan_{200} . (a) Time course of frequency change of three different measurements in QCM by the adsorption of pMan_{200} with 10 g L^{-1} at 15 C for 2 h. (b) XPS C (1s) spectrum of pMan_{200} immobilized substrate after the adsorption of the glycopolymer and water rinsing.

(Fig. 2 and Fig. S8-1, 8-2, ESI[†]). Although there were differences in the adsorption behaviour of each polymer by QCM, the XPS peaks were almost the same for all three polymers, suggesting that the thickness of the polymers on the gold substrate is almost the same regardless of the polymer. The weakly adsorbed glycopolymers on the substrate were removed by vigorously rinsing with water. The thiol-terminated polymers were considered to form pancake-like polymer monolayers due to the interaction between the gold substrate and the polymer. The thickness of the polymer layer was estimated to be around 2–5 nm based on previous reports.^{23,24}

The interaction between the glycopolymers was measured by the frequency change of QCM (Fig. 3(a)). In the case of pMan_{200} immobilized on the gold surface, the glycopolymer of pMan_{200} stacked up on the surface (Fig. S7-2, ESI[†]). Therefore, it was difficult to observe the amount of saturated adsorption of the glycopolymer pMan_{200} on the pMan_{200} thin layer. The PEG-terminated glycopolymers were prepared to prevent the aggregation of the glycopolymers.²⁵ The maximum frequency change of $\text{P}_{90}\text{Man}_{200}$ was more than ten times that of $\text{P}_{90}\text{Glc}_{200}$ and about four times that of $\text{P}_{90}\text{Gal}_{200}$ (Fig. 3(a) and Fig. S7-3, ESI[†]). The amount of glycopolymer bound followed the order: $\text{pMan}_{200}\text{-P}_{90}\text{Man}_{200} \gg \text{pGal}_{200}\text{-P}_{90}\text{Gal}_{200} > \text{pGlc}_{200}\text{-P}_{90}\text{Glc}_{200}$, which suggests a strong interaction between mannose clusters. Langmuir fitting was performed with the assumption that the interaction between the glycopolymer moieties was a one-to-one binding, though the interaction could occur cooperatively.²⁶ The apparent binding constant of $\text{pMan}_{200}\text{-P}_{90}\text{Man}_{200}$ was $4.7 \times 10^5 \text{ M}^{-1}$, and that of $\text{pGal}_{200}\text{-P}_{90}\text{Gal}_{200}$ was similar (Table 1 and Fig. S7-7, ESI[†]). The interactions of pMan_{200} with different glycopolymers ($\text{P}_{90}\text{Gal}_{200}$, and $\text{P}_{90}\text{Glc}_{200}$) were much weaker than those between pMan_{200} and $\text{P}_{90}\text{Man}_{200}$, though a certain level of interaction was observed between pMan_{200} and $\text{P}_{90}\text{Gal}_{200}$ (Fig. S7-6, ESI[†]). In addition, the interaction of pMan_{200} with PEG (PEG 4000) was negligible (Fig. S7-5, ESI[†]). These results indicate that the interaction of glycopolymers with mannose is specific to mannose clusters.

Fig. 3(b) shows the frequency change at each polymer concentration in the absence of calcium ions. The amount of glycopolymer adsorbed on the substrate is reduced in the

Fig. 3 The frequency change of QCM measurement at each PEG-terminated glycopolymer concentration. (a) Solvent condition; HEPES buffer with Ca^{2+} (HEPES: 10 mM, NaCl: 137 mM, KCl: 2.7 mM, CaCl_2 : 1.8 mM) and (b) HEPES buffer without Ca^{2+} .

Table 1 The apparent binding constants (K_a) between glycopolymers estimated by the Langmuir isotherm

Combination of glycopolymers	K_a (M^{-1})
pMan₂₀₀-P₉₀Man₂₀₀	4.7×10^5
pGal₂₀₀-P₉₀Gal₂₀₀	4.9×10^5
pGlc₂₀₀-P₉₀Glc₂₀₀	1.5×10^5
pMan₂₀₀-P₉₀Man₂₀₀ without Ca²⁺	2.0×10^5
pGal₂₀₀-P₉₀Gal₂₀₀ without Ca²⁺	n. d. ^a
pGlc₂₀₀-P₉₀Glc₂₀₀ without Ca²⁺	n. d. ^a

^a Not determined.

absence of calcium ions. The amount of glycopolymer bound followed the order **pMan₂₀₀-P₉₀Man₂₀₀** \gg **pGal₂₀₀-P₉₀Gal₂₀₀** and **pGlc₂₀₀-P₉₀Glc₂₀₀**, though the amount is reduced from that in the presence of calcium. The interaction between the glycopolymer and mannose (**pMan₂₀₀-P₉₀Man₂₀₀**) was obvious, and other polymer interactions were small and negligible. The apparent binding constant is $2.0 \times 10^5 M^{-1}$. The results indicate that the interaction between mannose clusters is significantly stronger than that between glucose and galactose, suggesting that the interaction between mannose clusters was contributed significantly by hydrogen bonding.

Turbidity measurements also supported that the interaction between each glycopolymer is dependent on the type of monosaccharide (Fig. 4).²⁵ The turbidity was recorded using glycopolymers (**pMan₂₀₀**, **pGal₂₀₀**, and **pGlc₂₀₀**). While **pMan₂₀₀** showed significant turbidity, **pGal₂₀₀** and **pGlc₂₀₀** did not. The increase in turbidity was caused by the interaction between the glycopolymers in aqueous solution and agreed with the QCM results, which indicated that a difference in the stereochemical structure of the saccharide affected the interaction.

These results indicate that the interaction between glycopolymers depends on the saccharide structure, which has a similar self-assembly capability of PEG-terminated glycopolymers. Only **P₉₀Man₂₀₀** showed a significant scattering, with its hydrodynamic diameter and polydispersity index (PDI) of 50 ± 3 nm and 0.17, respectively. In addition, the TEM observation of **P₉₀Man₂₀₀** also confirmed that it had a spherical structure with a 30 ± 5 nm diameter (inset of Fig. 5(a)).

Fig. 4 Turbidity measurement of **pMan₂₀₀**, **pGal₂₀₀** and **pGlc₂₀₀** and the chemical structure of monosaccharides. Turbidity of each glycopolymer was measured after dissolution in HEPES buffer at 1 g L^{-1} and standing at 15°C for 48 h.

Fig. 5 (a) DLS measurement of **P₉₀Man₂₀₀**, **P₉₀Gal₂₀₀** and **P₉₀Glc₂₀₀** and the TEM image of **P₉₀Man₂₀₀** (inset). (b) DLS measurement of **P₉₀Man₂₀₀** with (red) and without (black) Ca^{2+} .

These results indicated that among these three PEG-terminated glycopolymers, **P₉₀Man₂₀₀** can self-assemble in aqueous solution. Although all the monosaccharides (mannose, galactose, and glucose) have the same chemical formula, their self-assembly capability differs depending on their structure. In addition, the DLS measurements in the absence of calcium ions did not show any significant scattering in the case of **P₉₀Man₂₀₀**, which indicates that calcium ions are involved in the interactions between the glycopolymers and agrees with the results obtained by QCM measurement (Fig. 5(b)).

Interestingly, strong CCIs were observed with mannose clusters but not with galactose and glucose clusters. There is a possibility that the hydrophobicity of the polymer backbone and the triazole contribute to the interaction. However, in the case of polymers with glucose and galactose as the side chain, the interaction between the glycopolymers was significantly decreased, which shows that the interaction is caused by the mannose moiety. In our previous studies, the self-assembly of glycopolymers with mannose was mediated by hydrogen bonds and calcium coordination bonds, and not by hydrophobic interactions.²² At the same time, it is clear that the dense α -mannose along the polymer backbone induced intermolecular interactions.

Considering the previous results, the apparent binding constants (K_a) between the mannose clusters in this study are weaker than those between carbohydrate and lectin, but are comparable in strength.^{26–29} To date, CCIs have been observed only qualitatively in most studies, and there are few quantitative results. The reported CCIs are still limited to complex oligosaccharides. Abeyratne-Perera *et al.* also reported the formation of strong hydrogen bonds between mannobiose clusters using AFM. They reported a quantitative mannobiose cluster force which is comparable to the force of the CCI between specific combinations of oligosaccharides such as Le^x , which is different quantitative data to our binding constants.³⁰ The galactose interaction was comparable to the mannose interaction in the presence of calcium, which was similar to the CCI of lactose. The mannose interaction was remarkably strong even in the absence of calcium ions, and the contribution of hydrogen bonding was considered to be significant.

4. Conclusion

We evaluated the stereochemical dependence on the interaction between each glycopolymer moiety by QCM. The interaction between glycopolymers depended on the stereochemistry of the monosaccharide. The binding constants between glycopolymers carrying mannose were comparable to the carbohydrate–lectin recognition. The interaction was strongly affected by calcium ions. Comparing the self-assembly capability of the three kinds of PEG-terminated glycopolymers, only the mannose-carrying polymer could self-assemble in an aqueous solution. Mannose is abundant on the surface of viruses and pathogens, and the human body has many mannose receptors. In addition, the role of mannose has become very important because high mannose type *N*-glycans play a major role in protein quality control and transport. This mannose–mannose interaction could be an important interaction in biological systems. Mannose–mannose interactions have not been found before, and the bioinspired polymer made a significant contribution to the measurement.
