A heavily doped germanium pyramid array for tunable optical antireflection in the broadband mid-infrared range†

Bongkwon Son,^{‡,ab} Sang-Ho Shin,^{‡,a} Yuhao Jin,^a Yikai Liao,^a Zhi-Jun Zhao,^c Jun-Ho Jeong,^{id c} Qi Jie Wang,^{id a} Xincui Wang,^{id b} Chuan Seng Tan^{*ad} and Munho Kim^{id *a}

In this work, we report a heavily doped germanium (Ge) inverted pyramid array as a suitable candidate for tunable antireflection in the mid-infrared (MIR) range. Inverted Ge pyramid structures are formed by the metal-assisted chemical etching process. The heavy doping profile in a box shape is obtained via the KrF laser annealing process. The inverted pyramid serves as an effective antireflective surface structure, while the heavy doping layer acts as a high reflector, resulting from the modulated permittivity of Ge. It is observed that the reflectance of the inverted pyramid array made on undoped Ge is suppressed. In contrast, the reflectance of the pyramids after doping is increased in the wavelength range larger than 15 μm . The reflectance is consistent in the wavelength range smaller than 7 μm . A systematic study reveals that the doping concentration and depth are important parameters determining the ability to modulate the reflection spectra. The proposed heavily doped inverted Ge pyramid array paves the way toward a tunable and complementary metal-oxide-semiconductor-compatible antireflection structure in the MIR range.

Introduction

Surface reflection is caused by a large difference in the refractive index at the interface. It is one of the major limiting factors which reduce both absorption and transmission. Antireflection schemes are widely used to suppress the surface reflection in various optical systems such as cameras, solar cells, and bio- and molecular sensors.^{1–3} In particular, a mid-infrared (MIR) range, which ranges from 2 to 16 μm , covers atmospheric windows and the molecular fingerprint. The blackbody radiation at 300 K shows an emission peak around 10 μm . This property leads to vast applications in MIR optical sensing and communications such as civilian and military purposes in tracking and

positioning.⁴ Most MIR transparent materials possess a high reflective index larger than 2. The surface made of materials with a high refractive index results in low transmittance due to the surface reflection loss associated with a refractive index (n_e). The normal incident illumination in materials with sapphire optics ($n_e = 1.6$) results in a transmittance of 95%, while the transmittance decreases to 64% for materials with germanium optics ($n_e = 4.0$). Therefore, diverse antireflection techniques have been actively investigated to enhance the energy efficiency of optical systems.^{5–9}

Among them, the textured surfaces (*e.g.*, black silicon (Si) and germanium (Ge)) effectively reduce the reflection in visible and near-infrared ranges,^{10–12} leading to the development of high performance photonic and optoelectronic devices.^{13–15} As reported recently, the textured surfaces have the potential to provide efficient antireflection capability in the MIR range. For example, Si nanowires displayed a low reflection below 10% in the wavelength range up to 15 μm .¹⁶ In addition, the pyramid surfaces show low reflectance, which is similar to the nanowire surfaces.¹⁷ However, such antireflective structures suffer from low reflectance in the MIR range, which is critical for chemical detection, target recognition, and fundamental studies of cavity quantum electrodynamics.¹⁸

Alternatively, the metasurface is an attractive candidate, which can tune the reflectance and transmittance windows by

changing the geometric conditions. Micro- or nano-metal structures have been proposed to tune core spectral windows in the MIR range.^{19,20} In addition, the metal coatings on the textured surfaces result in high transmittance in the core spectral window and high reflectance out of the spectral window.²¹ However, the metals are lossy and some metals (e.g., Au and Ag) are not compatible with the complementary metal-oxide-semiconductor (CMOS) process. It is well known that the optical properties of semiconductors can be controlled by doping.^{22–24} In particular, heavily doped semiconductors have been introduced to replace conventional metals due to their plasmonic behavior in the MIR range.²⁵ Ge is one of the promising candidates to adjust the optical properties due to the small effective mass, low loss, and excellent CMOS compatibility. Heavily doped Ge with a doping depth of 1 μm displayed high reflectance in the MIR range.²⁶ However, the absorption in the doped layer is high in the MIR range due to the carrier scattering.

In this work, we propose a heavily doped inverted Ge pyramid array for tunable optical antireflection in the MIR range. The inverted pyramid array is formed by a hydrogen fluoride (HF)-free metal-assisted chemical etching (MacEtch) process. The heavy doping concentration in a box shape is obtained by ion implantation, followed by the KrF excimer laser annealing process. Optical reflectance is measured using a Fourier transform infrared spectrometer (FTIR) in the wavelength range from 2 to 25 μm . The undoped Ge pyramid displays a low reflectance below 0.3 in the wavelength above 15 μm and the reflectance is further reduced at a wavelength below 7 μm . The doped Ge pyramid array displays different behaviors: (1) high reflectance of 0.6 in the wavelength range of

15 to 25 μm and (2) low reflectance smaller than 0.1 in the wavelengths of 2 to 7 μm . A systematic study on the doped Ge pyramid array indicates that doping profiles (i.e., concentration and depth) alter the reflectance and transmittance spectra significantly. In addition, the spectra of heavily doped Ge with the inverted pyramid texture are comparable to the ones of noble metals. Therefore, the heavily doped Ge pyramid array can be an excellent candidate to replace the noble metals for optical antireflection due to its excellent tunability and CMOS compatibility.

Results and discussions

Fig. 1(a) represents the sheet resistance profile (SRP) analysis for the planar Ge samples after the laser annealing process. The doping profiles of three different cases (i.e., Doping A, B, and C) were varied by the dopant dose and the laser annealing conditions.²⁷ The box shapes of n-type doping profiles were obtained. This is because the laser annealing process caused an ultra-high temperature above 1000 $^{\circ}\text{C}$ in a shallow region in nanoseconds, resulting in a super-saturated doping concentration in a shallow region. The activated dopants were redistributed over a region of 100 nm for Doping B and C, while Doping A had the dopant distribution in 300 nm depth. The increase in the number of pulse irradiation caused deeper doping profiles. The slightly lower doping concentration at the surface should be attributed to oxygen in the air during the laser annealing.^{28,29} Notably, the Raman peak of the Ge transverse optical phonon was recovered to 300.6 cm^{-1} after the

Fig. 1 (a) n-type doping profiles of Doping A, B, and C. (b) Measured reflectance spectra of the intrinsic and doped Ge for Doping A, B, and C. (c) Calculated real (ϵ') and imaginary part (ϵ'') of Ge permittivity as a function of wavelength. The n-type doping profile with the doping concentration of 1×10^{19} and $4 \times 10^{19} \text{ cm}^{-3}$ were used for the calculation. (d) Simulated reflectance spectra of the intrinsic and doped Ge for Doping A, B, and C. The doping conditions for Doping A, Doping B, and Doping C are summarized in Table S1 (ESI †).

laser annealing process as shown in Fig. S1 (ESI[†]).³⁰ This indicates that Ge was recrystallized during the laser annealing process.³¹

Fig. 1(b) represents the reflectance spectra of the planar Ge samples. The reflectance spectrum of undoped planar Ge was measured to be 0.36 across the wavelength range measured. The reflectance spectra of the planar Ge with Doping A, B, and C were varied in the different wavelength regions. The reflectance near a wavelength of 3 μm dropped down to 0.21, while the reflectance in the wavelength range longer than 10 μm was higher than 0.40. The modulation of the reflectance spectra of the doped Ge is attributed to the changes in the permittivity of the Ge with different doping profiles because the doping profile can modulate the real (ϵ') and imaginary part (ϵ'')²² of Ge permittivity. The Drude model suffices to determine the permittivity. The Ge permittivity can be expressed by the following equations,³²

$$\epsilon' = \epsilon_{\infty} \left(1 - \frac{\omega_p^2 \tau^2}{1 + \omega^2 \tau^2} \right), \quad (1)$$

$$\epsilon'' = \epsilon_{\infty} \left(\frac{\omega_p^2 \tau^2}{\omega(1 + \omega^2 \tau^2)} \right), \quad (2)$$

where ϵ_{∞} , ω_p , ω , and τ are the high-frequency dielectric constant, plasma frequency, photon frequency, and relaxation time, respectively. The plasma frequency (ω_p) is determined by,

$$\omega_p = \sqrt{\frac{N e^2}{m * \epsilon_0 \epsilon_{\infty}}}, \quad (3)$$

where N , e , and ϵ_0 are the doping concentration, electron charge, and permittivity in free space, respectively. The estimated permittivity of Ge with the n-type doping concentration of 1×10^{19} and $4 \times 10^{19} \text{ cm}^{-3}$ was plotted as a function of wavelength in Fig. 1(c). The increase in doping concentration resulted in the negative real part of permittivity at a shorter wavelength range. However, the imaginary part of permittivity increased rapidly with the increasing wavelength, which makes doped Ge lossy at a longer wavelength range. It should be noted that the doping concentration for Doping A, B, and C led to the negative real part of permittivity in the MIR range, which is suitable for plasmon-based applications.^{23,24} Given the doping profiles in Fig. 1(a), the reflectance spectra can be calculated using eqn (1)–(3). Fig. 1(d) shows the calculated reflectance spectra of undoped and doped planar Ge *via* the finite-difference time-domain (FDTD) simulation. The undoped Ge displayed the consistent reflectance, while the doped Ge had a high reflectance at a longer wavelength range and low reflectance at a shorter wavelength range smaller than 10 μm . It is worth noting that the simulated reflectance spectra are in good agreement with the experimental ones shown in Fig. 1(b). The simulated reflectance of intrinsic Ge matches that of undoped Ge samples obtained by FTIR.

We introduce the inverted Ge pyramid texture to further reduce the reflectance in the wavelength range of 2 to 7 μm . It has been reported that the inverted pyramid texture displays

Fig. 2 (a) Fabrication process flow of the heavily doped inverted Ge pyramid array: A. Ge sample (grey) with the patterned photoresist (green). B. Ge sample with TiN-patterned surfaces (yellow) after the lift-off process. C. The MacEtched inverted pyramid array. The undercut etching was conducted to form a continuous pyramid structure. D. TiN was delaminated by undercut etching of Ge. E. The surface of the inverted pyramid array was doped by ion implantation and subsequent laser annealing. (b) Top view SEM image of the inverted pyramid Ge array. The scale bar is 5 μm . (c) Cross-sectional SEM image of the inverted pyramid array along the dashed line A–A' shown in (b). Scale bar is 2 μm . Note that the planar bottom region is due to sample cutting.

a lower reflectance than the upright pyramid one.³³ In addition, the surface area of the inverted pyramid structures is less than the upright pyramid structures, resulting in the low surface recombination loss.³⁴ Fig. 2(a) shows the schematic fabrication flow for the heavily doped inverted Ge pyramid array. The pristine undoped Ge samples were spin-coated with the photoresist and patterned by photolithography. Then, TiN was deposited on the photoresist-patterned surface *via* sputtering. The square TiN meshes with a square length of 4 μm and a spacing of 4 μm were obtained by the lift-off process. The MacEtch began in the open area where the Ge surface was exposed to etching solution.³⁵ TiN meshes served as a catalyst in the MacEtch process.¹⁷ The schematic process mechanism of the MacEtch is shown in Fig. S5(a and b) (ESI[†]). The undercut was induced by longer etching, resulting in the larger inverted pyramid size.³⁶ The additional etch time caused continuous inverse pyramid structures. The undercutting process is required to form continuous inverted Ge pyramids for low reflectance. The SEM image of the MacEtched inverted Ge pyramid with the undercut region is shown in Fig. S5(c) (ESI[†]). The width and height of the inverted pyramid were 6 and 5 μm , respectively. A core spectral window of reflectance and transmittance is demonstrated in the MIR range, resulting from the structure parameters of the inverted pyramid. Notably, the core spectral range can be adjusted towards a longer wavelength range by increasing the pyramid size.³⁷ The angle between the straight sidewall and the wafer surface was 54.7°, which corresponds to the angle between (100) and (111) orientations. The ion implantation was performed on both the planar and textured Ge surfaces, followed by the KrF laser annealing process. The phosphorous (P) dopant dose was selected to be 1×10^{15} and $4 \times 10^{15} \text{ cm}^{-2}$. The laser fluence of 825 mJ cm^{-2} for 1 and 10 pulse irradiation was used for laser annealing. Fig. 2(b and c) show the top-view and cross-sectional scanning

electron microscope (SEM) images of the inverted pyramid array, respectively.

Fig. 3 shows the reflectance and transmittance spectra of the inverted pyramid array made on both undoped and doped Ge. Simulated reflectance and transmittance spectra are also presented for comparison purposes. Fig. 3(a) shows the reflectance and transmittance spectra of the inverted undoped Ge pyramid. The reflectance spectrum of the planar Ge is included in the plot. The reflectance of the inverted Ge pyramid array was reduced in the broadband MIR range. Particularly, the reflectance was smaller than 0.10 when the wavelength was shorter than 7 μm . The reduction in the reflectance originates from the generation of lateral modes in the inverted pyramid array. Under normal illumination, the guided lateral mode is induced in the pyramid array. The induced lateral modes change the propagation path of the normal incident light, which results in the light scattering effect.^{27,36,38} The reflectance was continuously increased from 7 to 25 μm . Accordingly, the transmittance was 0.90 at 5 μm and it decreased to 0.70 at 25 μm . It is worth noting that the spectra of the inverted pyramid array follow the equation of $1 = R + T$ for intrinsic Ge because there is no absorption in this wavelength range, where R and T are the reflectance and the transmittance, respectively. The reflectance of the as-implanted inverted Ge pyramid array is shown in Fig. S2 (ESI[†]). No noticeable change was observed. Fig. 3(b–d) show the reflectance and transmittance spectra of the inverted Ge pyramid array with the doping profiles of Doping A, B, and C, respectively. The reflectance is consistent before and after the laser annealing process where the wavelength was smaller than 7 μm . However, the reflectance of three cases (*i.e.*, Doping A, B, and C) continuously increased to 0.33, 0.45, and 0.55 at 15 μm . They kept increasing and reached 0.40,

0.55, and 0.62, respectively, at 25 μm . The increased reflectance of the laser-annealed Ge results from the recrystallization during the laser annealing process. Accordingly, the transmittance at 25 μm was reduced when the wavelength increased from 2 to 25 μm . The surface morphology after the laser annealing was investigated *via* the transmission electron microscopy (TEM) analysis as shown in Fig. S3(a–g) (ESI[†]). A thin amorphous Ge layer was observed with a thickness less than 10 nm from the center, sidewall, and edge of the inverted pyramid in Fig. S3(e–g) (ESI[†]), respectively. In addition, single crystallinity maintained in depth larger than 10 nm, indicating that the damaged Ge caused by the ion implantation was recrystallized after the laser annealing process. Fig. 3(c and d) represent the reflectance spectra of the inverted pyramid with the doping profile of Doping B and C, respectively. In comparison with Doping A, the reflectivity of the pyramid array with Doping C is enhanced to be 0.6 in the wavelength above 15 μm . The enhanced reflectance of Doping C results from a high doping concentration. The real permittivity decreases significantly when the doping concentration increases. The reflectance of the inverted pyramid array with Doping B displays 0.55 at 25 μm . The change in the reflectance between Doping B and C originates from the doping depth. Notably, the reflectance of the inverted pyramid array with Doping B is higher than the ones with Doping A although the doping depth is shallow. This implies that the doping depth is the dominant factor which determines the reflectance. Notably, no noticeable change in the reflectance is observed at 200, 250, and 300 K because Ge permittivity is consistent (Fig. S4 (ESI[†])). It is also expected that the large incidence angle could result in high reflectance due to the high Fresnel coefficients.³⁹

Fig. 3 Reflectance and transmittance spectra of the inverted pyramid array for (a) intrinsic and doped Ge with the doping profiles of (b) Doping A, (c) Doping B, and (d) Doping C obtained by FTIR and FDTD. The reflectance spectrum of the undoped planar Ge is displayed in (a) as the grey line for comparison purpose. The doping conditions for Doping A, Doping B, and Doping C are summarized in Table S1 (ESI[†]).

Fig. 4 (a) Simulated reflectance and (b) transmittance spectra of the heavily doped inverted Ge pyramid array with different doping concentrations. The doping depth is fixed to be 300 nm. (c) Simulated reflectance and (d) transmittance spectra of the inverted Ge pyramid array with different doping depths. The doping concentration is fixed to be $2 \times 10^{19} \text{ cm}^{-3}$. The reflectance and transmittance spectra are obtained by the FDTD simulation.

It is important to investigate the variation in reflectance with different doping depth and concentration to optimize the doping profiles. Fig. 4(a and b) show the calculated reflectance and transmittance spectra of the inverted pyramid Ge array with the various doping profiles, respectively. The FDTD method was used to simulate the optical spectra in the wavelength range from 5 to 30 μm . The reflectance increased with doping concentration from intrinsic to $8 \times 10^{19} \text{ cm}^{-3}$ in the wavelength above 5 μm (Fig. 4(a)). The transmittance was decreased from 0.70 to nearly zero as shown in Fig. 4(b). In contrast, the transmittance was high in the wavelength range below 7 μm , which is comparable with the metal coatings on textured Si surfaces.²¹ However, the transmittance was reduced with increasing doping concentration in the short wavelength range. This is because heavily doped layers result in high absorption due to the enhanced extinction coefficient.²² The transmittance should be high enough in the core spectral window for high-efficiency antireflection. Thus, it should be required to choose the appropriate doping concentration to optimize the reflectance and transmittance. It should also be noted that doping depth can alter the reflectance and transmittance spectra of the pyramid array. The reflectance and transmittance spectra of the inverted pyramid Ge array can be adjusted by the doping depth as shown in Fig. 4(c) and (d), respectively. The doping concentration was selected to be $2 \times 10^{19} \text{ cm}^{-3}$ to study the effect of doping depth on the spectra. In Fig. 4(c), the reflectance was increased with the increasing doping depth in the wavelength range longer than 15 μm . Specifically, the reflectance was increased to 0.70 with the increasing doping depth up to 1000 nm, while the reflectance was maintained below 0.10 in

the wavelength range smaller than 7 μm . In addition, the transmittance was decreased with the increasing doping depth (Fig. 4(d)). The transmittance was smaller than 0.10 in the wavelength range longer than 15 μm , while the transmittance was larger than 0.70 in the wavelength range shorter than 7 μm . The absorption coefficient increases with increasing doping concentration in the MIR range due to the plasmonic behavior.²² Therefore, the enhanced absorption reduces the transmittance in the calculated wavelength range.

Conclusions

In conclusion, we have demonstrated an inverted Ge pyramid array combined with n-doping with various doping profiles for tunable antireflection in the MIR range. The inverted pyramid array and high doping concentrations are realized by the MacEtch and KrF laser annealing process, respectively. The inverted pyramid texture serves as the effective antireflective structure in the broad MIR wavelength range. In addition, the heavy doping profiles result in high reflectance due to the modulated permittivity of Ge. We also find that the reflectance and transmittance can be further modulated by the doping concentration and doping depth. It should be noted that the high reflectance higher than 0.60 is achieved in heavily doped pyramid structures with a doping concentration of $4 \times 10^{19} \text{ cm}^{-3}$. It has an increase in reflectance approximately two times that of the intrinsic one. The effect of doping profiles (*i.e.*, doping concentration and depth) on the reflectance and transmittance is thoroughly analyzed by the FDTD simulation. Our results provide a

robust and viable method to tune the reflectance and transmittance for advanced CMOS compatible MIR photonic and optoelectronic applications.

Experimental section

Formation of a Ge inverted pyramid array by MacEtch

Undoped Ge wafers were cleaned using acetone, isopropyl alcohol (IPA), and deionized (DI) water. The prebaked Ge pieces were spin-coated with a photoresist (AZ-5214) and patterned by photolithography. Subsequently, TiN was deposited on the photoresist-patterned surfaces *via* sputtering. The lift-off process was conducted in the acetone solution. The square TiN meshes with a square length of 4 μm and the space of 4 μm were obtained. An etching mixture consisting of potassium permanganate (KMnO_4) (1.27 mM) and DI water (15.82 mM) was used for the MacEtch process at 60 $^\circ\text{C}$ for 120 min.

Formation of heavy doping profiles

Phosphorus (P) ion implantation was performed at 25 keV for n-type doping at room temperature. The ion implantation dose was selected to be 1×10^{15} and 4×10^{15} cm^{-2} . The ion beam was tilted with 7° to the normal to the wafer surface. After the ion implantation, a KrF excimer laser was implemented for the dopant activation. A Roaster mode with a single spot size of $200 \times 200 \mu\text{m}^2$ was used. The laser fluence was selected to be 825 mJ cm^{-2} . The n-type profile for Doping A was obtained with 4×10^{15} cm^{-2} for single pulse irradiation. The doping profiles for Doping B and C were obtained with the dopant dose of 1×10^{15} and 4×10^{15} cm^{-2} for 10 pulses irradiation, respectively.

Finite-difference time-domain (FDTD) simulation

The real and imaginary parts of permittivity of Ge were obtained from ref. 20 and 28. A plane-wave light source was selected for normal incident illumination. A perfectly matched layer (PML) was used in the z-axis. The reflectance and transmittance monitors were positioned at the back side of the light source and at the Ge depth of 10 μm , respectively. The simulation window was applied in $6 \mu\text{m} \times 6 \mu\text{m}$ in the x-y plane and 20 μm in the z direction.

Characterization of the heavily doped Ge pyramid structure

Top and cross-sectional images of the inverted Ge pyramid array were taken using a field emission scanning electron microscope (FESEM, Sirion, FEI Netherlands). SRP was conducted to obtain the doping concentration of the planar Ge samples. The SRP method was performed in a $100 \times 100 \mu\text{m}^2$ area to obtain the activated doping concentration. The Bevel angle was 0.00192° with the step increment of 2 μm . The probe load was calibrated to be 2.6 g. The reflectance spectra were obtained using a Vertex 70v FTIR spectrometer in the wavelength range from 2 to 25 μm .
