Stable chemical enhancement of passivating nanolayer structures grown by atomic layer deposition on silicon†

Sophie L. Pain, ^{*a} Edris Khorani, ^a Tim Niewelt, ^{a,b,c} Ailish Wratten, ^a Marc Walker, ^d Nicholas E. Grant ^a and John D. Murphy ^{*a}

Incorporation of carrier-selective passivating contacts is on the critical path for approaching the theoretical power conversion efficiency limit in silicon solar cells. We have used plasma-enhanced atomic layer deposition (ALD) to create ultra-thin films at the single nanometre-scale which can be subsequently chemically enhanced to have properties suitable for high-performance contacts. Negatively charged 1 nm thick HfO₂ films exhibit very promising passivation properties – exceeding those of SiO₂ and Al₂O₃ at an equivalent thickness – providing a surface recombination velocity (SRV) of 19 cm s⁻¹ on *n*-type silicon. Applying an Al₂O₃ capping layer to form Si/HfO₂/Al₂O₃ stacks gives additional passivation, resulting in an SRV of 3.5 cm s⁻¹. Passivation quality can be further improved *via* simple immersion in hydrofluoric acid, which results in SRVs < 2 cm s⁻¹ that are stable over time (tested for ~50 days). Based on corona charging analysis, Kelvin probe measurements and X-ray photoelectron spectroscopy, the chemically induced enhancement is consistent with changes at the dielectric surface and not the Si/dielectric interface, with fluorination of the Al₂O₃ and underlying HfO₂ films occurring after just 5 s HF immersion. Our results show that passivation is enhanced when the oxides are fluorinated. The Al₂O₃ top layer of the stack can be thinned down by etching, offering a new route for fabrication of ultra-thin highly passivating HfO₂-containing nanoscale thin films.

Introduction

Crystalline silicon (c-Si) is the most successful photovoltaics technology to date accounting for >95% of solar cells currently produced.¹ Passivating films play an essential role in limiting charge carrier recombination at surfaces, hence increasing effective charge carrier lifetimes and solar cell efficiencies. Surface passivation is realized by a combination of chemical passivation of dangling bonds and field effect passivation to repel charge carriers away from the interface. Surface passiva-

tion quality can be quantified in terms of a surface recombination velocity (SRV) defined as:

$$SRV = \frac{W}{2} \left(\frac{1}{\tau_{\text{effective}}} - \frac{1}{\tau_{\text{bulk}}} \right) \quad (1)$$

where W is sample thickness, and $\tau_{\text{effective}}$ and τ_{bulk} are the effective and bulk carrier lifetimes, respectively. Alternatively, surface passivation quality can be quantified in terms of surface recombination current density ($J_{0,s}$), related to SRV by:²

$$J_{0,s} = \frac{q \cdot n_i^2 \cdot SRV}{N_b + \Delta n} \quad (2)$$

where N_b is the bulk dopant concentration, Δn is the excess carrier density, q is the elementary charge, and n_i is the intrinsic carrier density of Si.

For surface passivation of optically exposed regions of solar cells, it is common to use relatively thick (10 to 100 nm) passivating films which can also serve as antireflection coatings, and these may be single dielectric layers or stacks of multiple materials. A more innovative application of passivation layers is in carrier-selective contact structures.³ In this context, the

passivating layer or layer stacks must be ultra-thin (typically < 5 nm) to mitigate a significant increase in the series resistance of the device. To date, the record power conversion efficiency achieved by a single-junction silicon solar cell is a silicon heterojunction (HJT) based solar cell that incorporates ultra-thin (~5 nm) intrinsic a-Si:H as the passivating interlayer.⁴ SiO_x based passivating contacts, including the Tunnel Oxide Passivated Contact (TOPCon) and Poly-Silicon on Oxide (POLO), have also demonstrated a high potential in recent years.^{5,6}

Passivating dielectric thin films can be grown *via* chemical vapour deposition (CVD), thermal oxidation, sputtering, and atomic layer deposition (ALD).⁷ ALD is based on sequential self-terminating reactions⁸ and offers Angstrom-scale thickness control with a high degree of uniformity and conformality, even for complex surface geometries.⁹ Passivated emitter and rear cell (PERC) photovoltaics are the current industry standard and can often incorporate ALD-grown Al₂O₃ films.¹⁰ Al₂O₃ films possess negative fixed charges (~10¹²–10¹³ q cm⁻²),^{11,12} in contrast to many other dielectric passivating layers, such as SiN_x, which are positively charged.⁷ Al₂O₃ passivates extremely well when relatively thick (>10 nm) but passivates poorly when thin (<1 nm).¹³ There is a strong motivation to develop dielectrics with thicknesses at the single nanometre scale which also passivate well for new passivating contact structures.

Recent studies have identified HfO₂ as a versatile negatively charged passivating layer which can be grown by ALD.^{14,15} For relatively thick passivation layers (5 to 25 nm), passivation from HfO₂ is not competitive with that from Al₂O₃, with typical SRVs being ~5 cm s⁻¹ (ref. 14 and 16) and <1 cm s⁻¹,¹⁷ respectively. We have recently studied passivation by ultra-thin HfO₂ films and determined SRVs < 2.5 cm s⁻¹ for 2.2–3.3 nm thick films, with a negative fixed charge density on the order ~10¹² q cm⁻².¹³ Although this is promising and better than Al₂O₃ of similar thickness, when the HfO₂ thickness is reduced to ~1 nm – as required for passivating contacts – the SRV is ~19 cm s⁻¹. Work in this current paper aims to enhance this.

One widely used approach for enhancing the passivation of dielectrics is to apply capping layers. Positively charged SiN_x provides SRVs < 6 cm s⁻¹ and surface recombination current densities ($J_{0,s}$, an alternative measure of passivation^{2,18}) < 5 fA cm⁻² when capped with SiO_x,^{19,20} and SRVs < 3 cm s⁻¹ when capped with Al₂O₃.²¹ Recent results by Kersten *et al.* demonstrate that SiN_x capping layers incorporated into industrial PERC cells allow cell efficiencies of 23.7% to be achieved.²² SiN_x capping layers are often grown *via* plasma-enhanced CVD on top of thermal SiO_x or ALD-grown Al₂O₃. Preparing a stacked dielectric structure *via* a single growth method rather than two allows for more streamlined industrial production. Negatively charged Al₂O₃ has been identified as a promising capping layer for SiO₂,²³ ZnO,²⁴ and HfO₂.^{25,26} Al₂O₃ capping layers are thought to boost passivation by affecting hydrogen availability – either as a source or by preventing H effusion.^{23,24,27,28}

In this paper, we develop passivating stacks grown solely *via* ALD and assess the viability of Al₂O₃ as a capping layer for nanolayer HfO₂. We subsequently apply various wet chemical treatments as we observed improvement in nanolayer dielectrics in previous studies.²⁹ We also find that it is possible to thin-down the Al₂O₃ capping layer chemically, providing a new route to fabricating enhanced ultra-thin HfO₂ passivating films.

Results and discussion

Stacks involving ultra-thin (1 nm) HfO₂ interlayers

To determine the viability of Al₂O₃ capping layers for nanolayer HfO₂, three film structures were deposited at 200 °C onto 5 Ω cm 125–150 μm thick *n*-type Cz silicon wafers: (1) 1 nm HfO₂ (10 ALD cycles, denoted Si/HfO₂). The growth rate of HfO₂ under the conditions used in this work was characterised in our previous work¹³; (2) 1 nm HfO₂ capped with 30 nm Al₂O₃ (250 ALD cycles, denoted Si/HfO₂/Al₂O₃); and (3) 30 nm Al₂O₃ (denoted Si/Al₂O₃). Samples were annealed (“activated”) in air ambient in a tube furnace at temperatures between 350–600 °C for 30 min to improve the passivation. The passivation quality of both HfO₂ and Al₂O₃ are known to be dependent on annealing temperature, with optimal passivation achieved in both cases on annealing at 450–500 °C.^{11,30} Photoconductance decay lifetime curves for the three structures activated at 450 °C are shown in Fig. 1(a). SRVs defined according to eqn (1) at $\Delta n = 1 \times 10^{15}$ cm⁻³ are plotted as a function of activation temperature in Fig. 1(b).

The data in Fig. 1 for *n*-type Si confirm that thick Al₂O₃ provides better passivation than thin HfO₂, and that depositing 30 nm of Al₂O₃ on top of the HfO₂ has a significant positive impact on effective lifetime and hence passivation level. For activation annealing at 450 °C, an upper limit SRV of 18.6 cm s⁻¹ is found for thin HfO₂. Deposition of a 30 nm Al₂O₃ capping layer results in significant improvement, reducing SRV to 3.5 cm s⁻¹. The passivation achieved here for Si/HfO₂/Al₂O₃ is an order of magnitude better than previous reports²⁶ and corresponds to a single-side $J_{0,s}$ of 23.4 fA cm⁻². It is noted that a lower SRV (of 0.8 cm s⁻¹) is achieved for 30 nm Al₂O₃ alone. In the ESI (Fig. S1†), we show results for *p*-type Ga-doped silicon (same thickness and resistivity) and also find improvement upon deposition of a capping layer on 1 nm of HfO₂ on *p*-type silicon.

The improved passivation observed with Si/HfO₂/Al₂O₃ is in keeping with the reports of Polzin *et al.* and Dingemans *et al.*, who observe that an Al₂O₃ capping layer improves passivation for TOPCon and SiO₂ structures, respectively.^{27,28} The increased passivation is often attributed to the presence of hydrogen originating from the dielectric passivating the Si interface, hence reducing D_{it} .^{33,34} Oudot *et al.* also report improved chemical passivation on depositing HfO₂ atop thermal SiO₂, which they link to hydrogen diffusing to the Si/dielectric interface and passivating dangling bonds.³⁵ We would not expect any improvement in field-effect passivation

Fig. 1 (a) Effective lifetime curves for 1 nm Si/HfO₂ (orange squares), 30 nm Si/Al₂O₃ (green circles), Si/HfO₂/Al₂O₃ (purple triangles) stacks with 1 nm HfO₂ and 30 nm Al₂O₃ activated at 450 °C. Also shown is the intrinsic lifetime limit.³¹ Data for Si/HfO₂ were published previously.¹³ Substrates are high quality, ~150 μm thick, (100) orientation, 5 Ω cm, chemically etched *n*-type Cz silicon wafers. Samples with 1 nm HfO₂ were deposited onto *n*-type silicon from a nominally identical batch, excepting a reduced thickness of ~125 μm. (b) SRV determined at Δn = 1 × 10¹⁵ cm⁻³ for the same three configurations as in (a), with the same symbols used. The shaded regions correspond to the relative measurement uncertainty. No data in this figure arose from chemically treated samples.

from the applied Al₂O₃ capping layer, based on reports of HfO₂ acting as an “inert spacer” once Al₂O₃ is deposited upon it.²⁵

HF treatments of stacks with different HfO₂ interlayer thicknesses

We next present results which show the impact of HF-based chemical treatments on the passivation. It is known that Al₂O₃ capping layers for poly-Si can be removed without sacrificing passivation quality.^{24,33,34,36} Interestingly, we find here that partially removing Al₂O₃ films with dilute HF has a considerable positive impact on the surface passivation. Fig. 2(a) shows the effect of 5 s immersion in 1% HF on SRV for Si/HfO₂/Al₂O₃ stacks with 1 nm HfO₂ grown on *n*-type Si activated at different temperatures. The HF treatment provides a substantial increase in passivation level for all activation temperatures,

with SRVs < 2 cm s⁻¹ and single-side *J*_{0,s} of ~11.6 fA cm⁻² at 450 °C. The corresponding lifetime curves in Fig. 2(b) show no significant change in injection dependence (and hence passivation mechanism) following immersion. A similar increase occurs with Si/HfO₂/Al₂O₃ on *p*-type Si with a 5 s HF immersion which leads to a 1 cm s⁻¹ SRV reduction as shown in Fig. S1.†

Si/HfO₂/Al₂O₃ stacks incorporating HfO₂ layers of a more conventional thickness (10 nm, 100 ALD cycles) were also studied, with lifetime curves shown in Fig. 2(c). The passivation achieved for such stacks is similar to that with uncapped 10 nm Si/HfO₂ (average SRVs (single-side *J*_{0,s}) of 5.8 (19.6) versus 5.7 cm s⁻¹ (27.5 fA cm⁻²) for uncapped and capped 10 nm Si/HfO₂, respectively). This implies that the beneficial impact of the capping layer is less pronounced for thicker

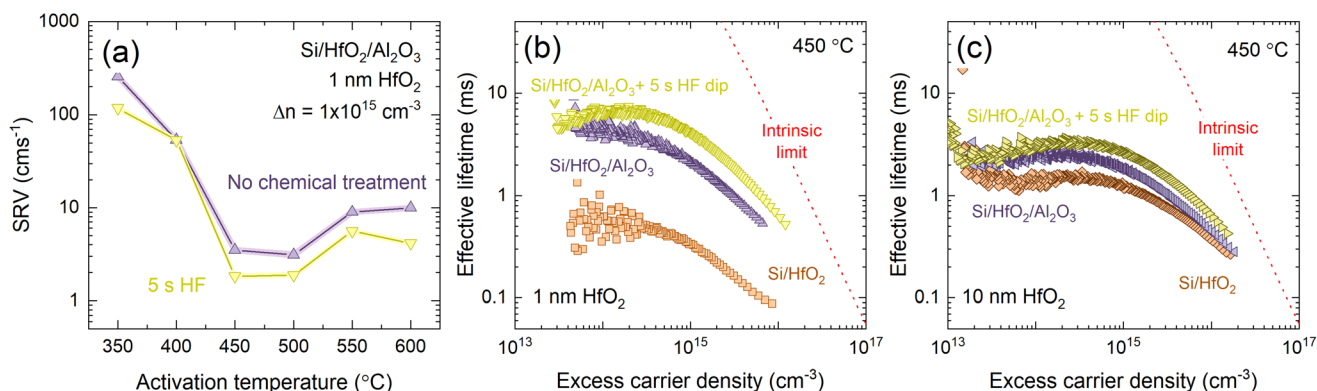

Fig. 2 (a) SRVs for Si/HfO₂/Al₂O₃ as-annealed (purple triangles) and following 5 s in HF (yellow triangles) as a function of annealing temperature. The shaded regions correspond to the relative uncertainty of SRV. (b) Effective lifetime curves for 1 nm Si/HfO₂ (orange squares) and Si/HfO₂/Al₂O₃, as-annealed at 450 °C (purple triangles) and following 5 s immersion in HF (yellow triangles). (c) Effective lifetime curves for 10 nm Si/HfO₂ (orange diamonds) and Si/HfO₂/Al₂O₃, as-annealed at 450 °C (purple triangles) and following 5 s immersion in HF (yellow triangles). Also shown is the intrinsic lifetime limit.³¹ All effective lifetime data are the average of five measurements and are assumed to be accurate to ±8%.³²

HfO₂ layers. Nevertheless, as shown in Fig. 2(c), 5 s HF immersion also enhances lifetime for these stacks, with a decrease in average SRV (single-side $J_{0,s}$) from 5.7 (27.5) to 3.6 cm s⁻¹ (16.7 fA cm⁻²). We also investigated reversing the stack structure, using 10 nm HfO₂ to cap 30 nm Al₂O₃. For this case, there is no significant improvement in passivation on application of the capping layer as shown in Fig. S2.†

Stability of enhanced passivation

For this chemical treatment step to be useful for photovoltaics or other devices, its effects must be stable with time and tolerant to subsequent processing at elevated temperatures. Earlier studies into HfO₂ passivation stated that for HfO₂-based layers to be incorporated into photovoltaic processing schemes, the temperatures they were exposed to could not exceed 400 °C.¹⁶ We have since shown that HfO₂-based films perform well up to ~500 °C,³⁰ but, nevertheless 400–500 °C temperature range provides a useful benchmark for testing thermal stability.

To assess temporal stability, samples were stored in a sealed Petri dish in ambient environment following HF immersion, and passivation quality was monitored at regular intervals. These results, relative to an untreated stack, are shown in Fig. 3(a). It is evident that the lifetime enhancement achieved with 1% HF is stable for at least 50 days, with no degradation onset observed. This stability far exceeds that of HF or other acidic treatment of bare silicon.^{37,38}

Fig. 3(b) shows SRVs for Si/HfO₂/Al₂O₃ stacks with 1 nm HfO₂ activated at 450 °C and sequentially re-annealed in air in a tube furnace for 30 min at temperatures increasing in 50 °C intervals. The two leftmost datapoints (at the 25 °C ‘re-anneal’ temperature) for HF-dipped Si/HfO₂/Al₂O₃ with 1 nm HfO₂ (yellow triangles) correspond to the average SRV before and after HF immersion. Both the HF-dipped stack and the untreated reference sample show a steady increase in SRV with

re-annealing up to a temperature of 250 °C. We then observe a sharp increase in the SRV when re-annealing at 300 and 350 °C. For higher annealing temperatures, we observe a recovery of passivation (decrease in SRV). The average passivation quality of HF-dipped stacks exceeds that of untreated Si/HfO₂/Al₂O₃ at all temperatures studied. Higher temperature ranges could not be studied, as above ~500 °C, HfO₂-based passivation quality is known to degrade,³⁰ and hence it would not be possible to separate contributions from the dielectric layers and the chemical treatment at these annealing temperatures.

The same experiment was conducted on Si/HfO₂/Al₂O₃ stacks with 10 nm HfO₂, with the data shown in Fig. 3(c). A trend broadly similar to the 1 nm HfO₂ case is found although following re-annealing at 300 °C, untreated stacks show slightly better passivation quality than HF-dipped stacks. The trends observed in SRV and $J_{0,s}$ are mirrored in the effective lifetime data from which these values were determined (Fig. S3†). As both $J_{0,s}$ and SRV describe surface recombination, the correlation between the extracted surface parameters and the overall effective lifetime further confirms this variation is surface-related, rather than bulk-related. Although the SRV equation assumes no change in bulk lifetime, $J_{0,s}$ makes no such assumption.

Similar experiments exploring the impact of subsequent re-anneals on uncapped Si/HfO₂ with 1 and 10 nm HfO₂ were also conducted, with results shown in Fig. S4 and S5,† respectively, demonstrating comparable trends. As the degradation–recovery cycle is observed for both thin and thick stacks, as well as uncapped thin and thick HfO₂, it is clearly neither caused by specific HfO₂ thickness nor by the stack architecture. Indeed, it is known to occur for other dielectrics, as a similar ‘re-activation’ can be seen with SiO₂, whereby high temperature processing reduces surface passivation, but it is recovered with subsequent annealing at 400 °C.²¹ The origins of this recovery in passivation at 400–450 °C are not fully clear.

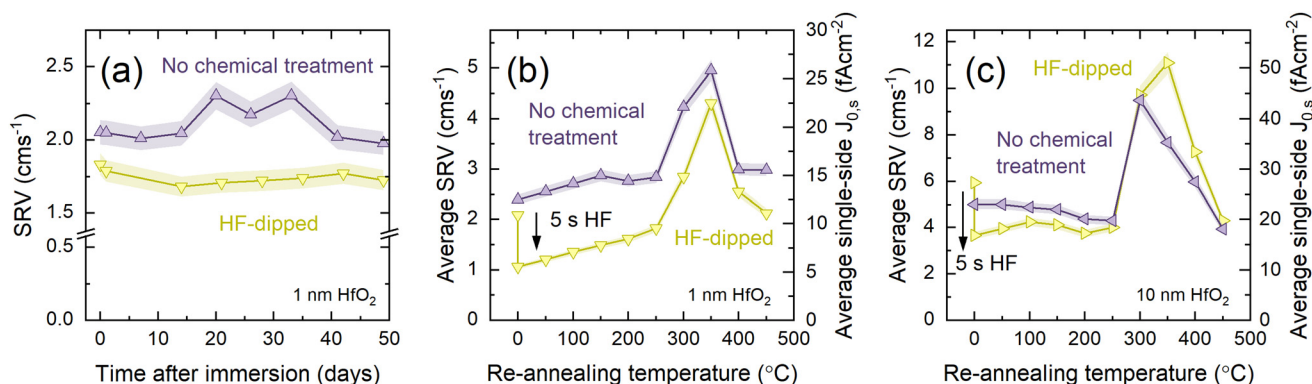

Fig. 3 (a) SRVs determined for Si/HfO₂/Al₂O₃ with 1 nm HfO₂ with no chemical treatment (purple triangles) and HF-dipped stacks (yellow triangles) as a function of time exposed to ambient conditions. Average SRVs (left axes) and corresponding single-side $J_{0,s}$ values (right axes) for parallel samples of Si/HfO₂/Al₂O₃ with (b) 1 nm and (c) 10 nm HfO₂ deposited on 5 Ω cm 150 μm n-type c-Si with no chemical treatment (purple triangles) and following 5 s immersion in 1% HF (yellow triangles). Effective lifetime (from which SRV is extracted at $\Delta n = 1 \times 10^{15}$ cm⁻³) was measured following re-annealing at temperatures between 50–450 °C for 30 min and reported SRV corresponds to the average of two parallel samples. In all cases, effective lifetime values (from which SRV is extracted) were the average of five measurements, and shaded regions correspond to relative uncertainty of SRV. Connections between the data points serve as a guide to the eye.

It could be associated with release of bound hydrogen within the passivation layers, which is mobile at these temperatures³⁹ or to short-range rearrangements of bonds 're-activating' the passivation, an effect also observed for Si/SiN_x/Al₂O₃ stacks.²⁸ Many industrial photovoltaic processing steps involve temperatures far above those considered in this study (although for shorter durations of time),^{10,21,40} but the tolerance of the stacks and even the wet chemical improvement discussed here to extended subsequent thermal processing is encouraging.

The passivation qualities achieved here are greater for Si/HfO₂/Al₂O₃ stacks with thin *versus* thicker HfO₂ and given the considerable recent interest in developing ultra-thin dielectrics as passivating interlayers or components of passivating contacts,^{41–43} the majority of this article will focus on Si/HfO₂/Al₂O₃ stacks with thin (1 nm) HfO₂.

Electronic origins of improved passivation

It is important to establish whether the origin of the HF-induced improvement in passivation is due to changes at the silicon/dielectric interface and/or changes at the dielectric/air interface. Therefore corona charging was employed to determine the charge fixed in the films and the level of chemical

passivation at the silicon–dielectric interface.⁴⁴ Successive corona charging was applied, with the quantity of charge (Q_{corona}) required to minimise $\tau_{\text{effective}}$ indicative of Q_{fixed} within the film.

Typical $\tau_{\text{effective}}$ *versus* Q_{corona} curves for chemically treated Si/HfO₂/Al₂O₃ stacks activated at different temperatures are shown in Fig. 4(a). Data for untreated stacks can be found in Fig. S6.† The extracted Q_{fixed} and τ_{minimum} values are shown in Fig. 4(b) and (c), respectively, for untreated stacks and those which had been subjected to a 5 s dip in HF. These respective quantities represent a measure of the charge in the films and the chemical passivation level.

In the case of stacks that were not chemically treated, a clear dependence of Q_{fixed} on activation temperature is apparent, consistent with the behaviour of uncapped HfO₂ films. The best passivation is observed for films activated at 450–500 °C, as is evident from Fig. 1, at which temperatures we observe Q_{fixed} of 2.5×10^{12} q cm⁻². This is lower than values observed for Si/HfO₂ or Si/Al₂O₃,^{11–13} but is consistent with reported interface fixed charge densities determined with capacitance–voltage (C - V) measurements for Si/HfO₂/Al₂O₃.²⁵ Extracted Q_{fixed} and τ_{minimum} for parallel samples of both

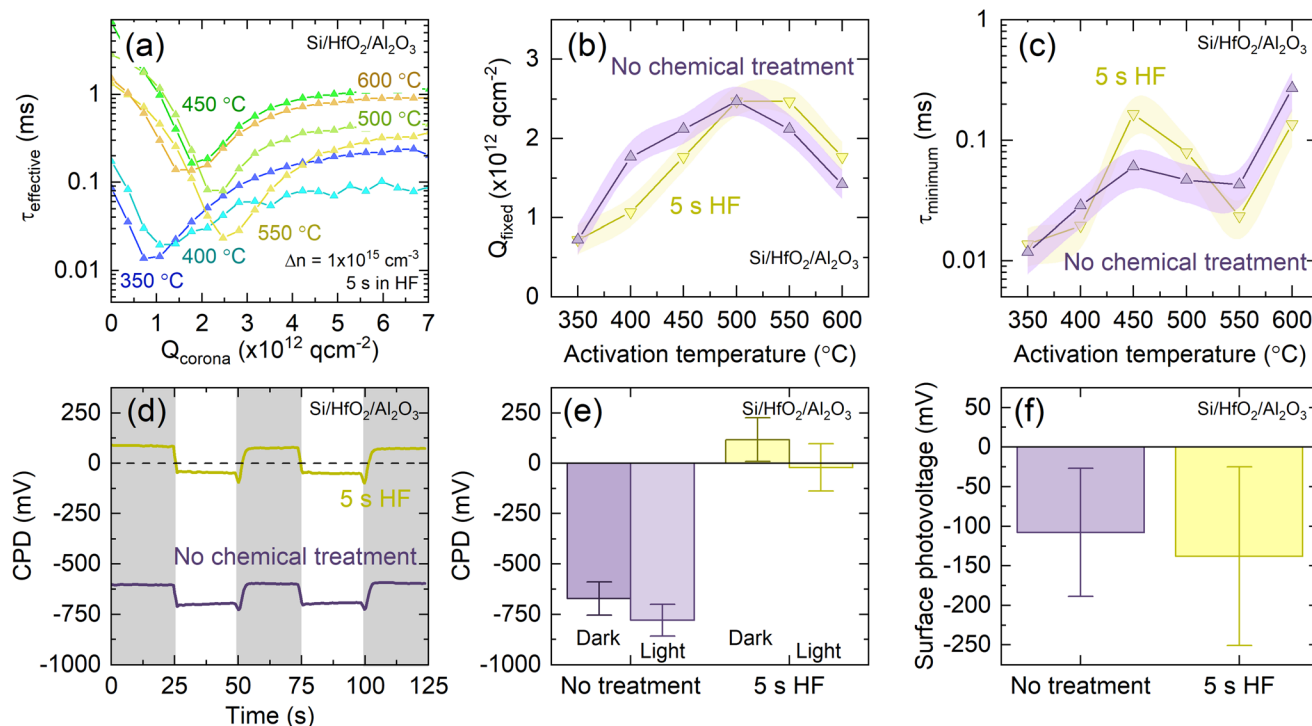

Fig. 4 (a) Effective lifetime as a function of Q_{corona} for Si/HfO₂/Al₂O₃ stacks with 1 nm HfO₂ activated at temperatures between 350–600 °C and immersed in HF for 5 s. (b) Q_{fixed} and (c) τ_{minimum} as a function of activation annealing temperature for Si/HfO₂/Al₂O₃ both untreated (purple) and following a HF dip (yellow). Shaded regions in (b) and (c) correspond to measurement uncertainty. Error bars in (b) correspond to a Q_{corona} of 1.85×10^{11} q cm⁻², 50% of Q_{corona} deposited in each charging step. Shaded regions in (c) correspond to experienced variation in effective lifetimes between Si/HfO₂/Al₂O₃ stacks. Connections between data points serve as a guide to the eye. (d) Representative surface photovoltage measurements, used to determine (e) CPD under dark conditions and illumination, and (f) SPV for both untreated stacks (purple) and stacks following a HF dip (yellow). Samples were activated at 450 °C. For each sample, at least five locations are measured in duplicate, and the reported values are the average of each point, with the CPD determined the mean of two darkness–illumination measurement cycles. The error bars are the mean standard deviation of these measurements.

untreated and HF-dipped Si/HfO₂/Al₂O₃ stacks are, broadly speaking, in agreement, as shown in (b) and (c).

The absence of any definitive change in Q_{fixed} or τ_{minimum} with HF treatment suggests that the factors contributing to the observed improvement in passivation are on the sample surface, rather than arising from changes at the Si/dielectric interface. This contrasts with the *alneal* process,^{45,46} whereby direct improvements are made to the Si/dielectric interface through use of an Al layer which is a considerable distance from the interfacial region.

Passivating stacks were also characterised by Kelvin probe to provide an understanding of changes at the dielectric/air interface upon HF-based treatment. The contact potential difference (CPD) is strongly dependent on the presence of charge on the dielectric surface.⁴⁷ Fig. 4(d) shows representative CPD data for Si/HfO₂/Al₂O₃ (untreated and HF-dipped) collected under a cycle of dark conditions (shaded regions) and under illumination (non-shaded regions). The absolute value of CPD increases after HF immersion, but as shown in Fig. 4(e), the magnitude of CPD change is consistent between stacks which were and were not treated with HF.

The surface photovoltage (SPV), which is the change in CPD upon illumination, can be used to assess the charge polarity in the dielectric stack, with a negative SPV expected for a negatively charged film.⁴⁸ Fig. 4(f) shows that the SPV magnitude is consistent between samples with and without HF treatment, demonstrating that the treatment does not modify the charge polarity or magnitude. Although SPV magnitude relates to charge magnitude, accurately quantifying charge levels based on SPV is non-trivial,⁴⁸ as SPV can be highly variable and dependent on material properties and surface defects.^{49,50} The SPV determined before and after HF treatment are of a similar magnitude, and within the experienced intra-sample variation. Importantly, in all cases the measured SPV was negative, demonstrating that the negative charge polarity is unchanged on treatment.

Changes in CPD that do not affect SPV shifts, as observed here, are reported to be associated with surface dipoles,^{48,51} which could be a potential contributor to the improved passivation following HF immersion. A shift in CPD without an accompanying shift in SPV has also been observed for *n*-type Si treated with benzoquinone-methanol and was attributed to differing surface dipoles before and after treatment.⁵² In particular, Yang *et al.*, who observe similar trends, attribute these to the presence of positive charges adsorbed onto the negatively charged surface (*cf.* our Al₂O₃ film), forming an interfacial dipole.⁵³

Some extrinsic passivation mechanisms, such as corona charging of dielectrics, can be removed by rinsing with deionised (DI) water⁵⁴ unless additional protective coatings are applied.⁵⁵ To assess whether the extrinsic passivation achieved here can be similarly removed, a Si/HfO₂/Al₂O₃ sample was immersed in DI water immediately after 5 s HF immersion. Data shown in Fig. S7† demonstrate no significant change in passivation quality on rinsing, as SRVs < 2 cm s⁻¹ are achieved after a HF dip whether or not it is preceded by a DI water

rinse, suggesting that the enhancement is resistant to further solution processing. KP results also show an increase in CPD which is not associated with a change in SPV, similar to that following HF immersion alone, suggesting that the surface dipoles inferred from KP persist after rinsing.

The enhancement observed here with Si/HfO₂/Al₂O₃ differs from reports of Si/SiO₂/Al₂O₃, where there is no notable change in passivation on removing the sacrificial Al₂O₃ capping layer.^{33,34,36} This implies that this improvement may be specific to the HfO₂ or Al₂O₃ layers used – or even to the full Si/HfO₂/Al₂O₃ stack. To assess this, we investigated the effect of 5 s HF immersion on single layer Si/HfO₂ and Si/Al₂O₃ samples. The layers were 1 and 30 nm thick respectively, to allow direct comparison with the behaviour of Si/HfO₂/Al₂O₃ stacks. No change in passivation quality was observed for Si/Al₂O₃, with SRVs of 1.1 cm s⁻¹ achieved both prior to and following the treatment. Effective lifetime data for this test can be found in Fig. S8.† In order to probe whether the high-quality passivation achieved with Al₂O₃ had potential for improvement with HF, samples with lower quality Al₂O₃ passivation were subjected to the same HF treatment, and no improvement in passivation was observed. Immersing Si/HfO₂ into 1% HF for 5 s was sufficient to remove the passivation (and the HfO₂ layer, as confirmed with XPS) completely. Rather than the increase in passivation quality (decreasing SRV) observed for Si/HfO₂/Al₂O₃, immersion of Si/HfO₂ results in an immeasurably high SRV. Thus, the observed improvement seems related to properties of the complete stack, not the individual layers. Changes in CPD could also be due to changes in the dielectric constant,³⁰ but this does not seem likely for a simple room temperature chemical treatment.

Although our experimental data suggest that the enhanced passivation is related to a charging effect at the dielectric surface, we cannot rule out the role of hydrogen and its ability to passivate the silicon–dielectric interface as an alternative explanation. In this case, the observed improvement in passivation following removal of the Al₂O₃ capping layer is similar to the “*alneal*” process, whereby Si/SiO₂ interfacial passivation is improved by depositing a sacrificial Al layer.^{45,46} Improved passivation following an *alneal* is reported to be due to Al catalysing production of atomic hydrogen,⁵⁶ or H₂ generation within the interfacial AlO_x film which forms between the Si and the Al, passivating the interface.²⁷ This process improves interfacial Si/dielectric passivation, even though the Al layer is tens of nanometres away from this interface, similar to the stack structures we use. Nevertheless, our electrical characterisation suggests that this is unlikely in our case.

Chemical analysis of HF-treated stacks and correlation with lifetime changes

We next perform experiments to assess the chemical composition of HF-treated Si/HfO₂/Al₂O₃ stacks. Fig. 5(a) shows XPS spectra for such stacks with 1 nm of HfO₂ immersed in HF for various times (up to 45 s), together with an untreated control. Prior to the HF treatment, the XPS spectrum is dominated by Al 2p and Al 2s peaks at ~75 eV and ~120 eV, respectively.⁵⁷ No

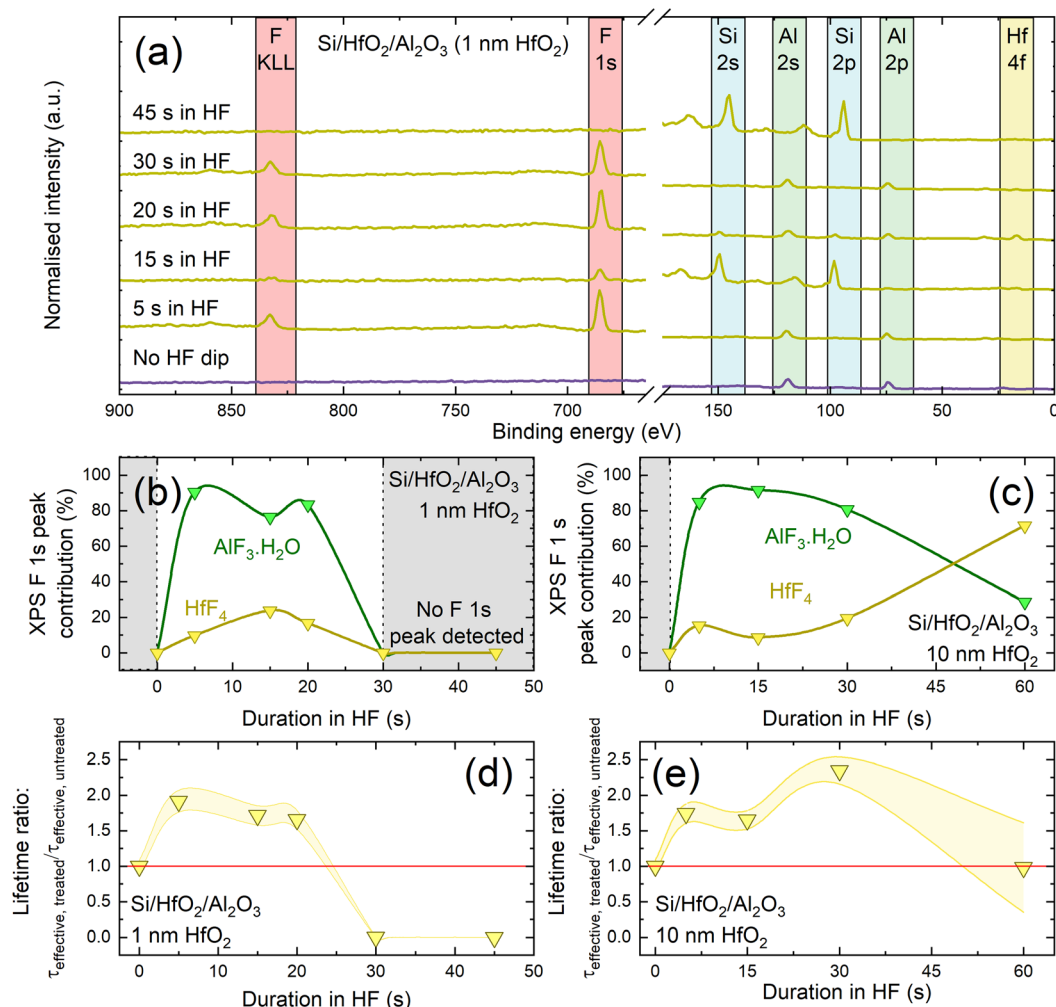

Fig. 5 (a) XPS survey scans for different HF immersion durations, with key XPS core levels identified. The small XPS contribution at ~ 110 eV visible after 30 s immersion corresponds to a plasmon loss feature for Si 2p, rather than an Al 2p signal. The separation between the main photoelectron peak and this bulk plasmon peak (and that of the Si 2s signal and its neighbouring satellite peak) of ~ 18 eV is consistent with reported plasmon loss signals.^{63,64} (b) and (c) Evolution of HfF_4 (yellow) and $\text{AlF}_3 \cdot \text{H}_2\text{O}$ (green) contribution to F 1s peak for $\text{Si}/\text{HfO}_2/\text{Al}_2\text{O}_3$ with 1 nm HfO_2 (b) and 10 nm HfO_2 (c) as a function of time in 1% HF. Lifetime enhancement as a function of immersion time of $\text{Si}/\text{HfO}_2/\text{Al}_2\text{O}_3$ stacks in 1% HF, determined as $\tau_{\text{effective, treated}}/\tau_{\text{effective, untreated}}$ for stacks with 1 nm HfO_2 in (d) and 10 nm HfO_2 in (e). Effective lifetime was extracted at $\Delta n = 1 \times 10^{15} \text{ cm}^{-3}$. Each point was the average of five measurements and has an assumed uncertainty of $\pm 8\%$.³² The lines between data points in (b)–(e) serve as a guide to the eye.

core levels corresponding to hafnium are detected (e.g., Hf 4f would be expected at ~ 17 eV for HfO_2 ⁵⁸), which is unsurprising given that the Al_2O_3 capping layer thickness (~ 30 nm) greatly exceeds the XPS photoelectron sampling depth (10 nm for hafnium 4f photoelectrons through an Al_2O_3 overlayer).^{59,60}

Since HF is known to etch Al_2O_3 ,⁶¹ increasing the HF dip duration will also increase the amount of Al_2O_3 removed. We determine the etch rate of Al_2O_3 in 1% HF as 1 nm s^{-1} (shown in Fig. S9†). Measured thickness across a sample following 5 s immersion in HF had a standard deviation of 2.3 nm (compared to 0.5 nm on non-HF dipped samples), suggesting that the capping layer is not etched uniformly in HF.

The XPS spectrum in Fig. 5(a) after 5 s in HF is consistent with the Al_2O_3 still being present, and the only notable change is the appearance of F peaks at ~ 685 eV and ~ 820 eV. Closer

inspection of the F 1s core level at ~ 685 eV allows deconvolution into two components, as shown in Fig. S10,† with the main contribution at ~ 686.4 eV corresponding to $\text{AlF}_3 \cdot \text{H}_2\text{O}$, and another smaller contribution at ~ 685.4 eV corresponding to HfF_4 .⁵⁷ It is surprising that hafnium-related signals are seen in XPS after relatively short HF immersion times when an intact Al_2O_3 capping layer is expected to remain. One explanation is the possible existence of pinholes in the Al_2O_3 layer which are widened by HF etching thus exposing the HfO_2 layer beneath. A similar observation was reported by Cheng *et al.*, who report pinholes in Al_2O_3 capping layers which are widened by an etching solution.⁶²

The relative HfF_4 and $\text{AlF}_3 \cdot \text{H}_2\text{O}$ contributions as determined by deconvoluting F 1s peak intensity as a function of HF immersion time are shown for stacks with 1 nm and

10 nm HfO₂ interlayers in Fig. 5(b) and (c), respectively. The corresponding lifetime enhancements relative to the untreated values are shown in Fig. 5(d) and (e). The impact of the HF treatment on passivation level varies with HfO₂ interlayer thickness. For 1 nm HfO₂ interlayers, the AlF₃·H₂O XPS signal contribution in Fig. 5(b) has a similar dependence on HF immersion time to the lifetime enhancement shown in Fig. 5(d). It could therefore be that the passivation enhancement relates to the extent of fluorination of the Al₂O₃ layer and the proportion of AlF₃·H₂O present. Interestingly when the dielectrics are reversed, Si/Al₂O₃/HfO₂ with 10 nm HfO₂ shows no improvement in passivation with HF immersion and also no F signals are observed in the XPS spectra (Fig. S11†).

The top layer of our conventional stacks is ~30 nm of Al₂O₃, thus 30 s in 1% HF should be sufficient to remove the Al₂O₃ layer. Indeed, XPS analysis of an Si/HfO₂/Al₂O₃ stack with a 1 nm HfO₂ interlayer after 30 s in HF, shown in Fig. 5(a), demonstrates that no Hf or Al peaks remain, while strong peaks are present from the silicon substrate. Data for stacks with 1 nm HfO₂ interlayers in Fig. 5(b) are only plotted for the first 20 s of HF immersion, after which XPS results indicate that the oxides have been etched away entirely. This is consistent with the lifetime data shown in Fig. 5(e) which show passivation is lost for these immersion times.

For 10 nm HfO₂ interlayers, the passivation quality of stacks is dependent on HF immersion time, as shown in Fig. 5(e). Stacks with thicker HfO₂ layers can be subjected to HF dips of up to 30 s with the passivation remaining enhanced. Corresponding lifetime curves are shown in Fig. S12.† The variation in passivation enhancement with 10 nm HfO₂ interlayers correlates with the variation in the HfF₄ signal up to 30 s, and the AlF₃·H₂O contribution after 30 s. From this it appears that the lifetime variation is related to fluorination of the dielectric layers. Beyond 30 s in HF, enhancements are lost, but the resulting effective lifetimes remains similar to the original level.

The difference in behaviour for ≥30 s of HF immersion for 1 nm and 10 nm interlayers is likely because of differences in crystallisation level between the HfO₂ films of different thicknesses. 10 nm thick films are known to crystallise upon

annealing at 450 °C,³⁰ becoming highly resistant to etching in HF.⁶⁵ ~1 nm HfO₂ films are unlikely to crystallise fully without being annealed at 700–800 °C,⁶⁶ and thus have not developed resistance to etching in HF.

A key aim of this work is developing enhanced ultra-thin passivating layers which have potential for passivating contacts. These passivating layers need to have low $J_{0,s}$,⁶⁷ with good passivating contacts/interlayers generally having $J_{0,s}$ values $\ll 10$ fA cm⁻²,^{67,68} as well as film thicknesses ideally $\ll 5$ nm.^{67,69} On this front, the most promising sample is Si/HfO₂/Al₂O₃ with 1 nm HfO₂ following 20 s HF immersion. By this point, approximately 20 nm of Al₂O₃ has been etched, resulting in a ~11 nm Si/HfO₂/Al₂O₃ stack with enhanced passivation. An SRV of 1.5 cm s⁻¹ is achieved, corresponding to a single-side $J_{0,s}$ of 5.8 fA cm⁻², which, to the best of our knowledge, is the first time a $J_{0,s}$ value $\ll 10$ fA cm⁻² has been measured for a HfO₂-based film. The passivation quality achieved here is well within the target for passivating contact materials and structures. The stack thickness (~11 nm) is not yet in the thickness range for passivating contacts or interlayers, but an optimised etching duration would provide thinner stack thicknesses. We have demonstrated that applying a capping layer and chemically thinning it provides a potential new route for fabrication of ultra-thin highly passivating nanoscale thin films.

Treatment of stacks with other chemical solutions

Chemical treatments other than HF were applied to Si/HfO₂/Al₂O₃ stacks to help elucidate the mechanisms of passivation enhancement. Stacks were treated for 5 s in either 1% HCl or SC1 ("Standard Clean 1", a hot (80 °C) mixture of NH₄OH, H₂O₂ and H₂O in a 1 : 1 : 5 ratio). These solutions, both a key part of industrial silicon cleaning and processing,⁷⁰ were selected as HCl is a protic acid (stronger than HF) but does not etch Al₂O₃, whilst SC1 is alkaline but etches Al₂O₃.⁶¹

Fig. 6(a) shows relative lifetime changes following treatment in HF, SC1, and HCl. As was the case for data in Fig. 3(a), samples were stored in a sealed Petri dish in ambient conditions, with passivation quality monitored at regular intervals. All three solutions enhance lifetime, but none are as stable as

Fig. 6 (a) Effective lifetime enhancement (defined as $\tau_{\text{effective, treated}} / \tau_{\text{effective, untreated}}$ at $\Delta n = 1 \times 10^{15}$ cm⁻³) as a function of time exposed to ambient conditions following chemical (HF/HCl/SC1) treatment, with an untreated control. Each point was the average of five measurements and has an assumed uncertainty of $\pm 8\%$.³² Connections between data points serve as a guide to the eye. (b) XPS survey scans of Si/HfO₂/Al₂O₃ with no chemical treatment (purple) and following 5 s in 1% HF (yellow), 1% HCl (blue) or SC1 (purple), with regions corresponding to key XPS core levels identified.

HF. The lifetime enhancement with HCl degrades within two weeks, eventually returning to the effective lifetime achieved prior to the HCl dip. The passivation gain with SC1 degrades considerably after one week, with a more gradual decay after this point. We also checked whether a DI water treatment influences passivation quality, but effective lifetime curves shown in Fig. S13† show this is not the case, hence it is the solute (not the common water solvent) which changes the passivation. SC1 is non-acidic, demonstrating that the protic nature of HF is not solely responsible for the improved passivation. Also, HCl does not etch Al₂O₃, so the enhancement is not due to etching alone. KP analysis presented in Fig. S14† demonstrates shifts in CPD which are not reflected in comparable shifts in SPV, supporting our surface dipole hypothesis.

The samples were also characterised with XPS, with survey scans shown in Fig. 6(b). XPS analysis highlights a difference in the substrate surface resulting from each chemical treatment. Although prominent F 1s and F KLL signals were seen following HF treatment, only a very weak Cl 2p peak was seen at ~200 eV following 5 s immersion in HCl.⁵⁷ This peak suggests some surface residue may remain following HCl immersion, similar to that seen following HF immersion. No such residue is detected following SC1 immersion, as evidenced by the lack of a N 1s signal at ~400 eV.⁵⁷

Experimental

Sample preparation

Chemical cleaning and dielectric deposition. Substrates for effective charge carrier lifetime characterisation and Kelvin probe measurements were high quality, ~150 μm thick, (100) orientation, monocrystalline 5 Ω cm resistivity, phosphorus-doped *n*-type Czochralski-grown silicon wafers with a chemically etched surface finish. Samples with 10 cycles of HfO₂ (determined in our prior work to correspond to ~1 nm HfO₂¹³) were deposited onto silicon from a nominally identical batch, excepting a reduced thickness of ~125 μm. For experiments on *p*-type silicon, Ga-doped, high quality, ~150 μm thick, (100) orientation, 5 Ω cm, chemically etched *p*-type Czochralski-grown silicon wafers were used.

Samples were prepared following a previously reported chemical cleaning and etching procedure.⁷¹ The final step in the cleaning process (immersion in 2% HF for 60 s) was modified to immersion in 1% HF/1% HCl for 5 min with no subsequent water rinse, as this has been found to improve final passivation quality.¹⁷ Coatings were grown *via* plasma-enhanced ALD using a Veeco Fiji G2 system with an external load lock. Films were deposited on both sides of each wafer at 200 °C using O₂ plasma, from trimethylaluminum (for Al₂O₃) and tetrakis(dimethylamido)hafnium (for HfO₂) precursors. Growth rates are reported by the supplier to be ~1.3 Å cycle⁻¹ (Al₂O₃) and ~1 Å cycle⁻¹ (HfO₂). A post-deposition anneal in air was performed for 30 min in a quartz tube furnace at temperatures between 350–600 °C.

Chemical treatments. Chemical treatments of stacks involved immersion in either 1% HF or 1% HCl at room temperature or SC1 at 75–80 °C (comprising DI water, 30% NH₄OH and 30% H₂O₂ in a 5 : 1 : 1 ratio). H₂O₂ (30–31% in water) was obtained from Technic Inc., NH₄OH (28–30% in water) from CMC Materials, HCl (37%) from BASF, and HF (48.5–50% in water) from Sigma-Aldrich. Samples were immersed for 5 s intervals, and blow dried with N₂ following immersion, prior to undergoing characterisation. Fresh solutions were used for the chemical treatment steps, reducing the likelihood of any contamination from prior cleaning processes.

HF safety considerations

Dilute HF is used in this work as a means to enhance passivation quality. It is important to note that HF is extremely corrosive and toxic,⁷² and must be handled only by those trained in HF handling, its hazards, and response in the event of exposure or spills. Exposure to HF and its fumes, even small quantities, can be fatal, and HF work should be conducted in a well-ventilated fume hood with appropriate personal protective equipment: face shield, apron, and HF-resistant gloves. HF etches glass, so HF work must be carried out in beakers compatible with HF.

Characterisation

Carrier lifetime measurements. Photoconductance decay lifetime measurements were performed at 30 °C using a Sinton Instruments WCT-120PL lifetime tester (software version 5.74). Measurements were averaged over five measurements and were performed using the quick decaying (0.02 ms) flash mode, except for low effective lifetime samples, which were measured using the slow-decaying (1.75 ms) flash. Measurements were made on 5 × 5 cm samples which is considered sufficiently large to avoid strong impacts of edge recombination on the experiment.⁷³ Effective lifetime measurements made using the quick decaying and slow decaying flash are assumed to be accurate to ±8% and ±11%, respectively.³²

Passivation quality was quantified in terms of SRV defined by eqn (1) with τ_{bulk} taken as the intrinsic (*i.e.*, radiative and Auger) limit using the parametrization of Niewelt *et al.*,³¹ taking photon recycling into account by assuming planar sample surfaces. For SRV extraction, we assume a constant τ_{bulk} as prior work using nominally identical Si substrates coated with HfO₂ found no change or degradation in bulk lifetime at the annealing temperatures used herein.³⁰ Assuming no extrinsic contribution to τ_{bulk} means values of SRV are upper limits. $J_{0,s}$ values, which have a relative uncertainty estimated to 10%,⁷⁴ were determined *via* an automated fit by the Sinton Lifetime Tester software (v.5.74) using a 2-point method without smoothing around $\Delta n = 1 \times 10^{15} \text{ cm}^{-3}$. A discussion on extracting $J_{0,s}$ from this region can be found in ref. 18. Our samples are generally coated with identical dielectric films on both sides, hence we state single-side $J_{0,s}$ values by dividing the extracted $J_{0,s}$ by 2.⁷⁵

X-ray photoelectron spectroscopy (XPS). XPS was performed at the Photoemission Research Technology Platform at the University of Warwick using a Kratos Axis Ultra DLD spectrometer. Samples were mounted on a non-magnetic, stainless-steel bar using electrically conductive carbon tape. The XPS spectrometer base pressure was $\sim 1 \times 10^{-10}$ mbar, and samples were pumped to $< 1 \times 10^{-6}$ mbar in the load lock before transfer, and then measured under a chamber pressure $< 1 \times 10^{-9}$ mbar. XPS measurements were performed using a monochromated Al K α X-ray (1.487 keV) source. Measurements were conducted at room temperature using a charge neutraliser and at a take-off angle of 90° with respect to the sample surface. Core level spectra were recorded from an analysis area of 300 $\mu\text{m} \times 700 \mu\text{m}$ by using a pass energy of 20 eV. Fitting procedures to extract peak positions and relative stoichiometries were performed using the Casa XPS software suite, linear backgrounds, and mixed Gaussian–Lorentzian (Voigt) line shapes. These were fitted and corrected using their corresponding sensitivity factors, considering the photoelectron mean free paths and photoionization cross sections of these core levels. The spectrometer work function and binding energy scale were calibrated using the Fermi edge and Ag 3d_{5/2} peak from a clean polycrystalline Ag sample measured prior to the experiments.

Kelvin probe force microscopy. Contact potential difference (CPD) measurements were made with a KP Technologies SKP5050 Kelvin Probe with a 2 mm gold-plated tip, based on the method of Baikie *et al.*⁷⁶ A Fiber-Lite DC-950 Quartz Tungsten Halide lamp was used for surface photovoltage (SPV) measurements. Surface photovoltage is defined as $\text{CPD}_{\text{illumination}} - \text{CPD}_{\text{dark}}$.

Corona charging. Corona charging was used to characterize the level of negative fixed charge in the dielectric films. Positive corona charging deposits extrinsic charge on the sample surface which offsets the built-in negative charges within the films. Eventually, successive corona charging counterbalances the intrinsic charge, with the quantity of deposited charge (Q_{corona}) required to reach this point providing an estimation of Q_{fixed} in the film.⁷⁷ A custom-built corona charge apparatus, similar to that described by Bonilla *et al.*,⁵⁵ was used to deposit charge on the thin films. The corona charge apparatus consisted of a sharp needle held at *ca.* 7 kV and positioned 7 cm from the sample. Samples were subjected to 3.5 V for 5 s on either side. The charge deposition rate was determined to be *ca.* 3.7×10^{11} q cm⁻² per 5 s of corona charging, based on the Kelvin Probe calibration method of Bonilla *et al.*⁴⁴ Following each corona charging treatment, effective lifetime was measured using the slow flash mode.

Spectral reflectance. Spectral analysis was used to calibrate the etch rate of Al₂O₃ in 1% HF using a Filmetrics F40-UV microscope, calibrated with a SiO₂/Si thickness standard. The F40-UV has a relative uncertainty of ± 1 nm.⁷⁸ To calibrate the Al₂O₃ etch rate, the average thickness of a ~ 20 nm Al₂O₃ film, deposited on polished 700 μm Si and annealed at 450 °C, was determined from three points across the sample. The average thickness was re-measured after 5 s intervals in 1% HF, and

from this, an etch rate of approximately 1 nm s⁻¹ was determined.

Conclusions

We have shown that Si surface passivation using HfO₂ films can be improved with a two-step process: (1) the application of an Al₂O₃ capping layer; and (2) immersion in dilute HF. Employing both steps ultimately achieves SRVs < 2 cm s⁻¹. Stacks of Si/HfO₂/Al₂O₃ with 1 nm HfO₂ treated with HF are stable for 50 days with thermal stability up to 450 °C.

The results presented in this work suggest the enhancement achieved is related to changes at the dielectric surface. XPS analysis showed direct evidence of fluorination of the dielectric layers following HF immersion, and this correlates with the effective lifetime and KP measurements, suggesting the enhancement may result from formation of surface charges. Nevertheless, we cannot rule out the role of hydrogen and its ability to passivate the silicon–dielectric interface. Thus, an alternative enhancement mechanism could arise due to dissociation of HF at the dielectric surface, subsequently enabling fluorination of the dielectric film (either HfO₂ or Al₂O₃) and thus freeing up H⁺ to interact with and passivate interface defects (as for the *aleneal* process^{27,46}). Direct detection of atomic hydrogen is experimentally very challenging. The observed fluorination could be indicative of hydrogenation, however this does not explain the enhancements observed when immersed in fluorine-free solutions (HCl- and NH₄OH-based solutions).

When the dielectric stack is reversed (*i.e.*, HfO₂ is the capping layer, rather than Al₂O₃) we observe neither a passivation enhancement nor any evidence of halogenation through XPS analysis. Similarly, when individual layers are chemically treated, we observe that the passivation level does not change. This work therefore demonstrates that when Al₂O₃ is deposited on top of (thin or thick) HfO₂, subsequent thinning down of the Al₂O₃ film substantially enhances the HfO₂ passivation, with attained SRVs and $J_{0,s}$ values being competitive with current passivating contacts, interlayers, and capping layer passivation schemes.

Author contributions

The research concept was devised by S.L.P., N.E.G., and J.D.M. Experimental work, sample processing, characterization, and data analysis were largely conducted by S.L.P. XPS data were collected and analysed by E.K. with assistance from M.W. N.E.G. developed the corona charging methodology. A.W. contributed to the development of HfO₂ passivation and temporal stability measurements. S.L.P., E.K., T.N., N.E.G., and J.D.M. contributed to discussions and data analysis. The manuscript was written by S.L.P. and J.D.M., with input from T.N., E.K and N.E.G.
