Alkaline local pH during a vigorous electrochemical CO<sub>2</sub> reduction reaction (CO<sub>2</sub>RR) can improve the activity and selectivity of CO<sub>2</sub>RR. However, it also leads to an alkalinity problem in that hydroxide ions obstruct the mass transfer of CO<sub>2</sub> to the active site, thereby limiting the current density. In this study, we introduce a silica-hydroxide cycle, which moderates the local pH by redistributing hydroxide ions, analogous to the carbonate-silicate cycle responsible for the drawdown of atmospheric CO<sub>2</sub> on Earth. In the membrane electrode assembly (MEA) of a CO<sub>2</sub> electrolyzer, SiO<sub>2</sub> undergoes weathering due to the high local pH and consequently consumes OH<sup>−</sup>, reducing the pH within the MEA. The dissolved silicate ions move to the membrane and are almost regenerated to SiO<sub>2</sub> with release of OH<sup>−</sup>. Geological and spectral observations suggest that the silica-hydroxide cycle reduces the local pH thereby enhancing mass transfer of CO<sub>2</sub>, breaking the limitation of current density for CO<sub>2</sub>RR. Our work proposes new chemical approaches to increase current density, mainly improved by physical methods, and contributes valuable insight for improving a variety of electrochemical systems.

## Broader context

The electrochemical CO<sub>2</sub> reduction reaction (CO<sub>2</sub>RR) is viewed as a promising approach to attain carbon neutrality while generating valuable fuels and chemicals. Enhancing the current density in CO<sub>2</sub>RR presents a significant challenge for the efficient production of chemicals on a meaningful scale, which is essential for economic viability. Recently, various mechanical approaches have enhanced the performance of CO<sub>2</sub>RR through enhancing the mass transfer of CO<sub>2</sub>, playing a pivotal role in improving the current density. Nevertheless, in the high current density region, the hydroxide ions created during the reaction form a local alkaline environment, which converts CO<sub>2</sub> to carbonate ions, hindering the mass transfer of CO<sub>2</sub> to the catalyst surface and limiting the current density for CO<sub>2</sub>RR. This study delves into the role of SiO<sub>2</sub> in the electrochemical CO<sub>2</sub>RR regarding the silica-hydroxide cycle, which moderates the local pH by redistributing hydroxide ions. This mechanism draws a parallel with the silicate-carbonate cycle, which plays a crucial role in the natural sequestration of atmospheric CO<sub>2</sub> on Earth, thus offering a novel avenue for breaking the current density limitation of CO<sub>2</sub>RR through controlled pH management.

## Introduction

The electrochemical CO<sub>2</sub> reduction reaction (CO<sub>2</sub>RR) is viewed as a promising solution for achieving carbon neutrality while producing valuable fuels and chemicals.<sup>1–3</sup> Increasing the current density for CO<sub>2</sub>RR poses a significant challenge for the mass production of chemicals while ensuring economic feasibility.<sup>4,5</sup> Recently, various mechanical approaches, including gas-phase CO<sub>2</sub>, device design, gas diffusion electrode (GDE), membrane electrode assembly (MEA), pressurized system and nanosized catalyst, have successfully enhanced the performance of CO<sub>2</sub>RR *via* enhancing mass transfer of CO<sub>2</sub>, playing a pivotal role in improving the current density.<sup>6–17</sup> Under high current density regime coming from a recently developed system, an intriguing phenomenon, called local pH,

clearly appeared for CO<sub>2</sub>RR. The hydroxide ions generated from the reaction create a local alkaline environment at the electrode, promoting CO<sub>2</sub>RR *via* reducing the hydrogen evolution reaction (HER) and modulating binding energies for the intermediates.<sup>18–24</sup> Nevertheless, some studies addressing local pH have indicated an alkalinity problem in that hydroxide ions block the mass transfer of CO<sub>2</sub> to the catalyst by converting carbonate, limiting the current density for CO<sub>2</sub>RR.<sup>25,26</sup> The alkalinity problem of CO<sub>2</sub>RR can be validated using alkali cation effects. Numerous experimental and theoretical investigations reveal that a larger size of alkali cation exhibits smaller hydration number at the Helmholtz layer and lower  $pK_a$  values near the electrode, mitigating the local pH phenomenon.<sup>27–29</sup> The current density of CO<sub>2</sub>RR according to alkali cation was assessed in a CO<sub>2</sub> MEA electrolyzer using Ag black sprayed GDE (Fig. 1a and Fig. S1–S3, ESI<sup>†</sup>). CsHCO<sub>3</sub> electrolyte demonstrated a significantly higher maximum current density for CO<sub>2</sub>RR than KHCO<sub>3</sub> electrolyte. To delve into the pH reaction environment of the cathode in the MEA electrolyzer, *in situ/operando* Raman spectroscopy and gas analysis of the anode were carried out (Fig. 1b and c). In the Raman spectra for the KHCO<sub>3</sub> electrolyte, the carbonate peak disappeared at current densities exceeding 400 mA cm<sup>-2</sup>, while the carbonate peak persisted at a current density of 800 mA cm<sup>-2</sup> using CsHCO<sub>3</sub> electrolyte. The *in situ/operando* Raman spectroscopy focused on the catalyst surface. Thus, the disappeared carbonate peak indicates that

the catalyst surface possesses high alkalinity with almost no carbonate ions resulting from reaction with OH<sup>-</sup> and CO<sub>2</sub> gas. These observations indicate that the larger size of Cs cations alleviates the local pH phenomenon at high current densities. The gas ratio of CO<sub>2</sub> and O<sub>2</sub> for the anode side decreased below 2 was observed at 400 mA cm<sup>-2</sup> for KHCO<sub>3</sub> and 800 mA cm<sup>-2</sup> for CsHCO<sub>3</sub>. The changes of gas ratio by current density are well explained by the schematic illustration in Fig. 1d. The ratio of CO<sub>2</sub> and O<sub>2</sub> is close 2 in the current density region showing high faradaic efficiency (FE) for CO, indicating the main carbonate ion transfer from cathode to anode.<sup>30,31</sup> The decreased CO<sub>2</sub> at the anode shows transfer of hydroxide ions from the cathode, suggesting a highly alkaline reaction environment at the cathode sufficient to prevent hydroxide ion contact with CO<sub>2</sub>. Additionally, as shown in the *in situ/operando* Raman results in Fig. 1b, the mass transfer of CO<sub>2</sub> to the catalyst layer is impeded by high local pH, further limiting the current density for CO<sub>2</sub>RR. This suggests that, besides physical properties that can be improved by mechanical methods, the chemical reaction environment also plays a significant role in current limitations. Thus, chemical approaches, such as cation effects, are essential for enhancing current density in CO<sub>2</sub>RR. The key for a chemical strategy is alleviating local pH by rebalancing CO<sub>2</sub> and hydroxide ion concentration at the cathode.

In nature, Earth's CO<sub>2</sub> is balanced by various carbon cycles including the carbonate-silicate cycle.<sup>32–35</sup> This

geochemical process redistributes CO<sub>2</sub> in the atmosphere to the oceans and land by rainwater, silicate weathering, carbonate precipitation and sedimentation, resulting in drawdown of atmospheric CO<sub>2</sub> (Fig. 1e) The stored CO<sub>2</sub> in land is redistributed to the atmosphere by volcanism. In this study, we aim to break the current density limitation for CO<sub>2</sub>RR

using silica oxide *via* a silica-hydroxide cycle, similar to the carbonate-silicate cycle. The unique silica properties allow distribution of the high OH<sup>−</sup> concentration at the catalyst surface to the other cathode side, reducing the elevated local pH at the catalyst surface and facilitating mass transfer of CO<sub>2</sub> for CO<sub>2</sub>RR.

## Results and discussion

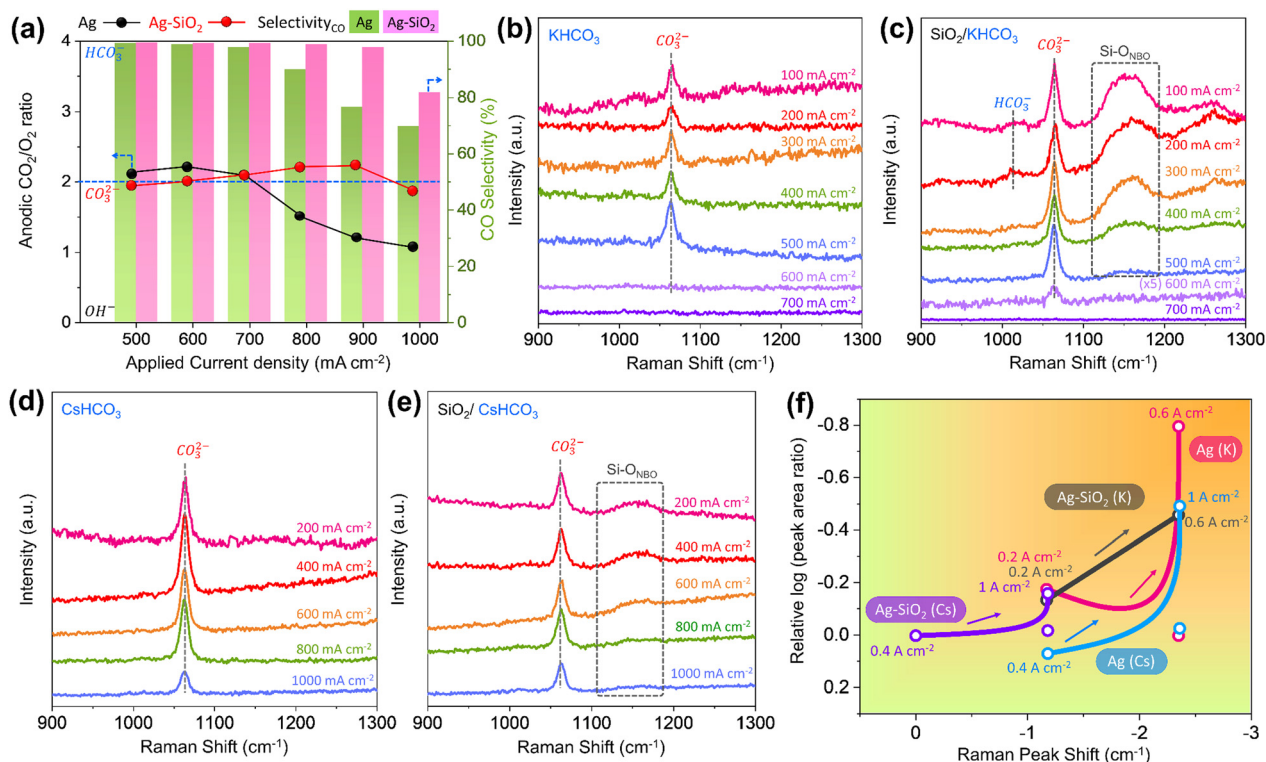

### Effects of SiO<sub>2</sub> on current density for CO<sub>2</sub>RR

An Ag–SiO<sub>2</sub> electrode was fabricated on a GDE by spraying ink of a mixture of SiO<sub>2</sub> nanopowder and commercial Ag black (Fig. S4–S6, ESI†). Fig. 2a illustrates SEM and SEM-EDX mapping images of the Ag–SiO<sub>2</sub> electrode, indicating that Ag black and SiO<sub>2</sub> nanoparticles are well dispersed on the GDE substrate. The effects of SiO<sub>2</sub> for CO<sub>2</sub>RR performance were studied by using an anion exchange membrane (AEM) zero-gap electrolyzer with 0.1 M CsHCO<sub>3</sub> anolyte and humidified CO<sub>2</sub> gas (Fig. 2b, d and Fig. S7, ESI†).<sup>36,37</sup> At an applied current density below 600 mA cm<sup>−2</sup>, both the Ag and Ag–SiO<sub>2</sub> electrodes show similar CO<sub>2</sub>RR performance, with a high FE<sub>CO</sub> exceeding 90%. However, above an applied current density of 700 mA cm<sup>−2</sup>, the FE<sub>H<sub>2</sub></sub> of the Ag electrode drastically increased with rising current density, resulting in a maximum current density for CO of 549 mA cm<sup>−2</sup>. On the other hand, the FE<sub>CO</sub> for the Ag–SiO<sub>2</sub> electrode remained at over 80% and the selectivity for CO (H<sub>2</sub> and CO, SE<sub>CO</sub>) was nearly 100% at an applied current density until 1 A cm<sup>−2</sup> while suppressing the HER. The difference of FE<sub>CO</sub> and SE<sub>CO</sub> at a high current density region would come from production of formate (Fig. S8, ESI†). The maximum current density of the Ag–SiO<sub>2</sub> electrode for CO reached a value of 806 mA cm<sup>−2</sup>, implying that additional SiO<sub>2</sub> to the Ag black

electrode contributed to breaking the current density limitation for CO<sub>2</sub>RR. Exploring the effects of varying SiO<sub>2</sub> ratios indicates the necessity for an optimal amount of SiO<sub>2</sub> (Fig. S9, ESI†). To confirm the physical effects, an Ag–TiO<sub>2</sub> electrode was fabricated using similar size of TiO<sub>2</sub> instead of SiO<sub>2</sub> (Fig. S10, ESI†). Ag–TiO<sub>2</sub> exhibits a similar limiting current density to Ag for CO<sub>2</sub>RR. The results of Ag–TiO<sub>2</sub> and the comparable ECSA value for both the Ag and Ag–SiO<sub>2</sub> electrodes show that the impact of SiO<sub>2</sub> does not originate from physical properties (Fig. S11 and S12, ESI†). A similar phenomenon of breaking the maximum current density limit for CO<sub>2</sub>RR was observed using 0.1 M KHCO<sub>3</sub> anolyte at lower current densities (Fig. 2e and Fig. S13, ESI†). To validate the SiO<sub>2</sub> effects for high current density, chronopotentiometry tests were conducted at a current density of 700 mA cm<sup>−2</sup> where the effect of SiO<sub>2</sub> is seen (Fig. 2f and Fig. S14, ESI†). FE<sub>CO</sub> of the Ag electrode was close to 80% and rapidly decreased after 3 h. In contrast, the Ag–SiO<sub>2</sub> electrode demonstrated stable cell voltage and consistent FE<sub>CO</sub> above 90% for 12 h, suggesting that the effects of SiO<sub>2</sub> are not an instant phenomenon and could serve as a sustained strategy.

### The origin of SiO<sub>2</sub> effects in breaking current density limitation

To elucidate the origins of SiO<sub>2</sub> effects that overcome the current density limitation of CO<sub>2</sub>RR, the cathode reaction

**Fig. 3** The analyses of the role of SiO<sub>2</sub> in modulating the cathode reaction environment. (a) CO<sub>2</sub>/O<sub>2</sub> ratio at the anode in a zero-gap electrolyzer using Ag–SiO<sub>2</sub> with 0.1 M CsHCO<sub>3</sub>. (b) *In situ/operando* Raman spectroscopy results for the Ag electrode in 1 M KHCO<sub>3</sub> electrolyte. (c) *In situ/operando* Raman spectroscopy results for the Ag–SiO<sub>2</sub> electrode in 1 M KHCO<sub>3</sub> electrolyte. (d) *In situ/operando* Raman spectroscopy results for the Ag electrode in 1 M CsHCO<sub>3</sub> electrolyte. (e) *In situ/operando* Raman spectroscopy results for the Ag–SiO<sub>2</sub> electrode in 1 M CsHCO<sub>3</sub> electrolyte. (f) Summary of *in situ/operando* Raman spectroscopy results using carbonate Raman peak shifts and carbonate peak intensity ratios for both Ag and Ag–SiO<sub>2</sub> electrodes in KHCO<sub>3</sub> and CsHCO<sub>3</sub> electrolytes. Reference points for peak shift and intensity: KHCO<sub>3</sub>, 100 mA cm<sup>−2</sup>; CsHCO<sub>3</sub>, 200 mA cm<sup>−2</sup>.

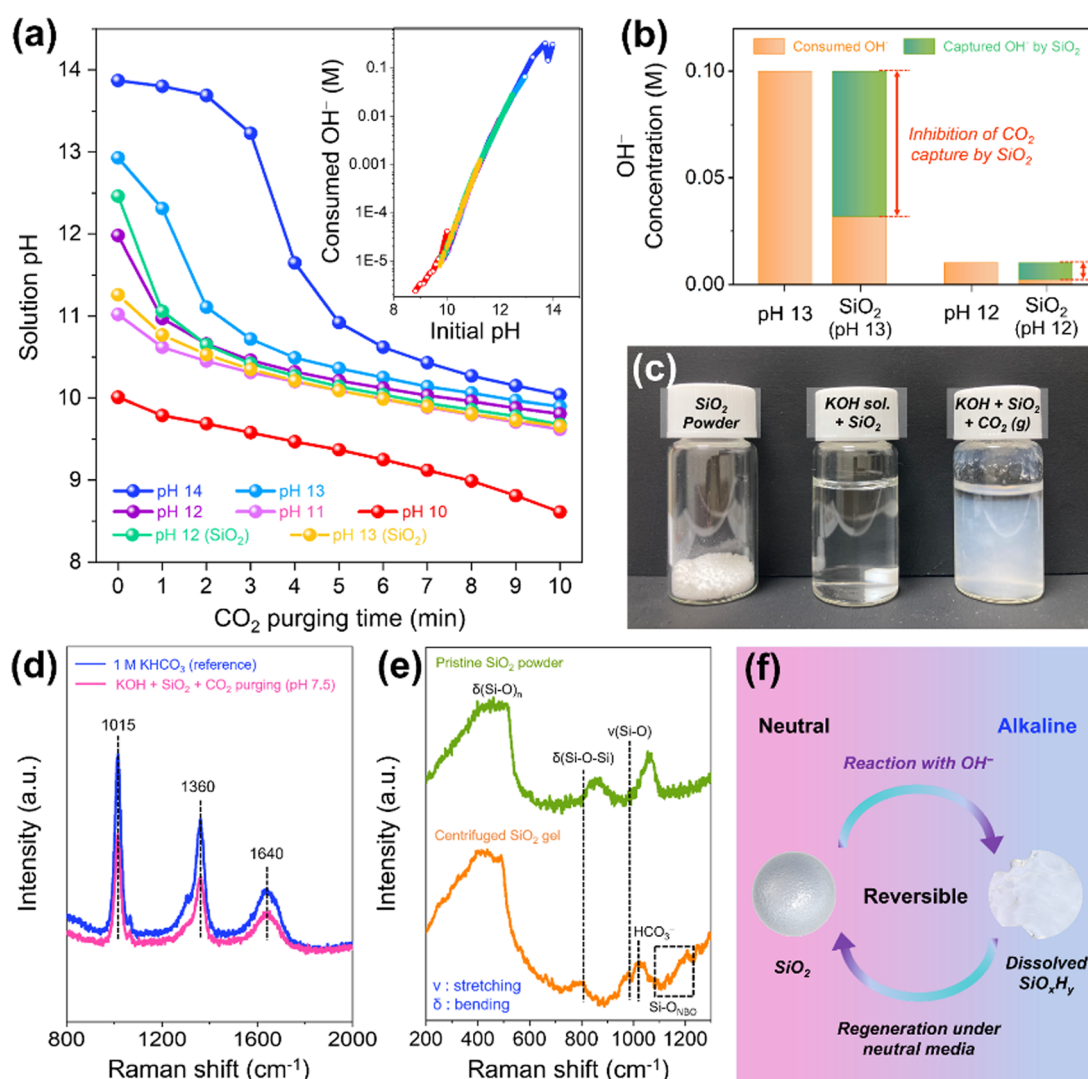

environment in the MEA electrolyzer was investigated using gas analysis of the anode and *in situ/operando* Raman spectroscopy using a GDE. For the Ag-SiO<sub>2</sub> electrode, the gas composition ratio of CO<sub>2</sub> to O<sub>2</sub> remains near 2 within a current density range of 500–1000 mA cm<sup>-2</sup>. However, for the Ag electrode, this ratio drops to almost 1 when the current density exceeds 800 mA cm<sup>-2</sup> (Fig. 3a). This suggests that SiO<sub>2</sub> mitigates the local pH effects stemming from high current densities.

To more directly observe the reaction environment of the cathode, *in situ/operando* Raman spectroscopy was carried out using a customized GDE Raman cell (Fig. S15, ESI†).<sup>38</sup> To estimate the pH of the cathode according to current density, we constructed two calibration curves for ranges of 9–13 and 13–14 (Fig. S16–S20, ESI†). Even at a low current density of 100 mA cm<sup>-2</sup>, the bicarbonate peak for all *in situ/operando* Raman

spectra nearly disappears, signifying pronounced local pH effects in the GDE.<sup>23</sup> In a KHCO<sub>3</sub> electrolyte, the carbonate peak disappears for the Ag electrode at a current density of 600 mA cm<sup>-2</sup> (Fig. 3b). Conversely, for the Ag-SiO<sub>2</sub> electrode, a minor carbonate peak persists at the same current density, indicating that SiO<sub>2</sub> mitigates local pH effects, reminiscent of cation effects (Fig. 3c). The Ag-SiO<sub>2</sub> electrode also exhibited a similar trend in CsHCO<sub>3</sub> electrolyte. The carbonate peak for the Ag electrode is lower than that for the Ag-SiO<sub>2</sub> electrode at a current density of 1 A cm<sup>-2</sup> (Fig. 3d and e).

For the Ag-SiO<sub>2</sub> electrode, peaks corresponding to Si-O<sub>NBO</sub> (where NBO is non-bridging oxygen) were observed at a current density between 100 and 400 mA cm<sup>-2</sup>, hinting at the onset of SiO<sub>2</sub> degradation in alkaline conditions (Fig. S21, ESI†).<sup>39,40</sup> For intuitive representation of local pH under various conditions,

**Fig. 4** Analysis of SiO<sub>2</sub> in CO<sub>2</sub>RR media. (a) Change in solution pH for various initial pH solutions under CO<sub>2</sub> purge, plotted against CO<sub>2</sub> purging time (Inset: Quantity of OH<sup>-</sup> consumed based on current pH). (b) Variation in OH<sup>-</sup> concentration during CO<sub>2</sub> purging, attributed to OH<sup>-</sup> capture due to the presence of SiO<sub>2</sub>. (c) Images of pristine SiO<sub>2</sub> powder, SiO<sub>2</sub>-dissolved KOH solution, and an opaque gel obtained within the SiO<sub>2</sub>-dissolved KOH solution after CO<sub>2</sub> purging. (d) Raman spectra comparing 1 M KHCO<sub>3</sub> solution (reference), and the CO<sub>2</sub>-purged, SiO<sub>2</sub>-dissolved KOH solution (containing the opaque gel). (e) Raman spectra comparing pristine SiO<sub>2</sub> powder and centrifuged SiO<sub>2</sub> gel obtained from the opaque gel within the CO<sub>2</sub>-purged solution. (f) A schematic illustrating the reversible behavior of SiO<sub>2</sub> species during the reaction.

we summarize the *in situ/operando* Raman results based on two parameters: the log-transformed relative peak area ratio of the carbonate peak and its shift (Fig. 3f). The carbonate peak shift is expected to be related to the Stark effect or cation concentration.<sup>41–43</sup> However, since there is no carbonate intermediate in the CO<sub>2</sub>RR mechanism on the Ag surface, we assumed that this peak shift was caused by cation concentration. The calibration results unequivocally show that carbonate peak area, which is related to carbonate concentration, is correlated to pH and peak shift corresponds to cation concentration (Fig. S22 and

S23 and Note S2, ESI†). Based on calibration data, the estimated local pH results from *in situ/operando* Raman spectra are shown in Fig. S24 and Table S1 (ESI†). While the alkalinity of the Ag electrode increased with current density, the Ag–SiO<sub>2</sub> electrode in comparison retained its pH, underscoring the role of SiO<sub>2</sub> in the suppression of local pH effects.

### Behavior of SiO<sub>2</sub> in CO<sub>2</sub>RR system

In an effort to understand the effects of SiO<sub>2</sub>, it is necessary to observe the behavior of SiO<sub>2</sub> in a medium that simulates the

Fig. 5 Geological and spectral observations of silica-hydroxide cycle in MEA CO<sub>2</sub> electrolyzer. (a) A schematic representation of the carbonate-silicate geochemical cycle occurring during electrochemical CO<sub>2</sub> reduction reaction on Ag–SiO<sub>2</sub>. SEM images and EDS elemental mapping of the Ag–SiO<sub>2</sub> electrode before (b) and after (c)–(e) reaction (c: 900 mA cm<sup>-2</sup> for 20 min; (d) and (e): 1 A cm<sup>-2</sup> for 20 min) in MEA CO<sub>2</sub> electrolyzer.

reaction environment for a CO<sub>2</sub> MEA electrolyzer. To verify the neutralization of local pH by CO<sub>2</sub>, we purged the CO<sub>2</sub> gas into solutions of various pH and measured the pH every minute (Fig. 4a). As the duration of the CO<sub>2</sub> purge increased, the solution's pH decreased, owing to the reaction of OH<sup>−</sup> ions with CO<sub>2</sub>, resulting in carbonate ions. The amount of consumed OH<sup>−</sup> with CO<sub>2</sub> is proportional to pH of solution, highlighting the alkalinity problem that blocks the transfer of CO<sub>2</sub> to active sites due to the high local pH. When the SiO<sub>2</sub> nanopowder was mixed with alkaline solution of pH 12 and 13, SiO<sub>2</sub> dissolved, leading to a decrease in the solution's pH. Regardless of the presence of SiO<sub>2</sub>, the rate of OH<sup>−</sup> consumption by CO<sub>2</sub> was invariably proportional to the pH of the solution, implying that CO<sub>2</sub> gas capture by OH<sup>−</sup> is suppressed by SiO<sub>2</sub> (Fig. 4b). Interestingly, suspensions were detected in SiO<sub>2</sub>-dissolved solution following an extended CO<sub>2</sub> purge (Fig. 4c). The analysis of collected solution and precipitate (by centrifugation) after 2 h of CO<sub>2</sub> purge (the pH of solution reached 7.5) demonstrates separation of SiO<sub>2</sub> and KHCO<sub>3</sub> solution,<sup>44</sup> suggesting almost reversible behavior of SiO<sub>2</sub> (Fig. 4d, e and Fig. S21, S25, ESI<sup>†</sup>). When the SiO<sub>2</sub> nanopowder was mixed with solutions of 0.1 M KHCO<sub>3</sub> (pH 8.65) and 1 M KHCO<sub>3</sub> (pH 8.69), the pH remained almost unchanged at 8.70 (Fig. S26, ESI<sup>†</sup>). The presumed reaction involving SiO<sub>2</sub> is depicted in Fig. 4f. In alkaline media, SiO<sub>2</sub> dissolved and converted to silicate ions by reaction of OH<sup>−</sup>. These silicate ions then precipitate as SiO<sub>2</sub> under neutral conditions with release of OH<sup>−</sup> due to low solubility.<sup>44–46</sup> We hypothesize that this cycle involving SiO<sub>2</sub> and hydroxide also takes place in the CO<sub>2</sub> MEA electrolyzer.

### The silica-hydroxide cycle in MEA CO<sub>2</sub> electrolyzer

The mechanism of breaking the current limitation by SiO<sub>2</sub> in a CO<sub>2</sub> electrolyzer is hypothesized as being due to the reversible cycle of SiO<sub>2</sub> between alkaline and neutral media, carrying OH<sup>−</sup> ions (Fig. 5a). We postulate that this silica-hydroxide cycle decreases the local pH of the electrode surface by increasing hydroxide distribution, thereby enhancing mass transfer of CO<sub>2</sub> for CO<sub>2</sub>RR. This process of silica-hydroxide cycle is similar to the silicate-carbonate cycle that maintains the CO<sub>2</sub> level in the atmosphere. When a vigorous CO<sub>2</sub>RR occurs in the MEA CO<sub>2</sub> electrolyzer, the pH of catalyst surface is presumed to be that of an alkaline medium in the range of pH 11–14 by *in situ/operando* Raman spectroscopy. Concurrently, the pH of the AEM is expected to be neutral owing to abundant transported carbonate ions, indicating a suitable environment for the reversible silica-hydroxide cycle.

To demonstrate the silica-hydroxide cycle in the MEA CO<sub>2</sub> electrolyzer, silica weathering, evidence of the silica-hydroxide cycle, was monitored using geological and spectral observations with SEM. The pristine Ag–SiO<sub>2</sub> electrode clearly delineates the boundary between SiO<sub>2</sub> and Ag nanoparticles (Fig. 5b and Fig. S27, ESI<sup>†</sup>). After CO<sub>2</sub>RR, this boundary becomes less distinct in SEM images (Fig. 5c and Fig. S28, ESI<sup>†</sup>), and this blurring intensifies as the current density increases (Fig. S29–S33, ESI<sup>†</sup>). Nevertheless, SiO<sub>2</sub> is well dispersed in the electrode,

similar to before the reaction. Notably, no discernible difference in Ag nanoparticles dependent on SiO<sub>2</sub> is observed, suggesting that SiO<sub>2</sub> has no effect on the chemical state and structure of Ag (Fig. S34–S39, ESI<sup>†</sup>). These outcomes corroborate the hypothesis of silica weathering under high current densities. To further substantiate the presence of dissolved silicate ions and the regeneration of SiO<sub>2</sub>, EDS mapping was employed to discern the state of SiO<sub>2</sub>. When the dissolved silicate ions dried with alkali cations, hydrous alkali silica gel is formed.<sup>47</sup> This hydrous alkali silica gel is observed in certain regions of the electrode, signifying the presence of dissolved silicate ions (Fig. 5d and Fig. S40, ESI<sup>†</sup>). The accumulation of regenerated SiO<sub>2</sub> on the Ag electrode, the final step of the silica-hydroxide cycle, is clearly shown in Fig. 5e. SiO<sub>2</sub> appears on the Cs carbonate precipitate that is generated during or post-CO<sub>2</sub>RR, implying regenerated SiO<sub>2</sub>.

Under high cathodic currents, SiO<sub>2</sub> weathering is triggered by high local pH, leading to a decrease in pH by consuming OH<sup>−</sup> at the catalyst surface. The dissolved silicate ions, not reacted with CO<sub>2</sub>, move to the AEM side.<sup>48,49</sup> The dissolved silicate ions are converted to SiO<sub>2</sub> with counterbalancing release of OH<sup>−</sup> under neutral conditions at the AEM and the converted SiO<sub>2</sub> is redistributed on the electrode. However, the silica-hydroxide cycle is not completely reversible in the MEA electrolyzer owing to the AEM, which is highly permeable to anions and cations. SEM-EDS mapping cross-section images after reaction show that the majority of SiO<sub>2</sub> remains in the cathode, but a small amount of SiO<sub>2</sub> has been moved to the AEM and anode (Fig. S41, ESI<sup>†</sup>). To eliminate the regeneration step at the AEM, 1 M KOH was used for MEA test instead of 0.1 M CsHCO<sub>3</sub> at a current density of 700 mA cm<sup>−2</sup>. ICP-OES analysis shows that 67.6% of SiO<sub>2</sub> is preserved on the cathode with the silica-hydroxide cycle but, without the regeneration step, 5.8% of Si remained on the cathode. These results show that the regeneration step, which is critical for reversibility of the silica-hydroxide cycle, functions in a real MEA electrolyzer. This silica-hydroxide cycle reduces the concentration of OH<sup>−</sup> that captures CO<sub>2</sub>, thereby enhancing mass transfer of CO<sub>2</sub> to catalyst active sites and breaking the limitation of current density.

## Conclusions

Our study introduces a novel strategy to overcome the limitation of the current density for CO<sub>2</sub>RR by a chemical cycle approach, without the need for physical modification. Hydroxide ions generated from CO<sub>2</sub>RR elevate the local pH. While this can enhance selectivity, it also hinders the transfer of CO<sub>2</sub> by forming carbonate ions, thus imposing a current density limitation for CO<sub>2</sub>RR. Therefore, controlling the local pH is crucial for achieving a high current density. On Earth, atmospheric CO<sub>2</sub> levels are reduced *via* carbon cycles, such as the silicate-carbonate cycle. This geological carbon cycle redistributes CO<sub>2</sub> from the atmosphere to rocks through silicate weathering. Similarly, the silica-hydroxide cycle derived using

SiO<sub>2</sub> causes a reduction in the local pH of the catalyst surface in the MEA CO<sub>2</sub> electrolyzer. SiO<sub>2</sub> weathering is triggered by high local pH, and silicate ions transport the hydroxide ions near the AEM without CO<sub>2</sub> capture at the catalyst surface and reconvert to SiO<sub>2</sub>. This cycle of SiO<sub>2</sub> enhances the mass transfer of CO<sub>2</sub>, breaking the current density limitation for CO<sub>2</sub>RR. Considering commercialization, the future goals of the silica-hydroxide cycle should be focused on enhancing the reversibility in real MEA electrolyzers. This chemical cycle strategy also observed on Earth holds a wide-ranging applicability across various systems, offering fresh insights for augmenting their efficiency and breaking their limitations.

## Experimental procedures

### Materials and chemicals

Silver nanopowder (Alfa Aesar, APS 20–40 nm, 99.9%), silicon dioxide nanopowder (Sigma-Aldrich, 10–20 nm, 99.5% trace metal basis), titanium(IV) oxide nanopowder (Sigma-Aldrich, 21 nm primary particle size (TEM), ≥99.5% trace metals), Nafion 5 wt% ionomer solution (Sigma-Aldrich), isopropanol (DAEJUNG, 99.5%), and iridium(IV) oxide (Alfa Aesar, premium, 99.99%; Ir 84.5% min) were used as received, without further purification. Carbon paper (Fuel Cell Store, Sigracet 39BB) and platinized titanium screen (Fuel Cell Store) were employed as substrates for cathodic and anodic electrodes, respectively. These substrates were cut to the desired size using a home-made punch. KHCO<sub>3</sub>, which was used as the electrolyte, was procured from Sigma Aldrich (ACS reagent, >99.7%). The AEM used was sourced from Dioxide Materials (Sustainion X37-50 grade RT).

### Preparation of Ag-based electrode for cathode

The Ag black, Ag-TiO<sub>2</sub> and Ag-SiO<sub>2</sub> electrodes were fabricated by spraying catalyst ink onto a gas diffusion layer (GDL) at 70 °C. For the Ag-SiO<sub>2</sub> catalyst ink, 90 mg of commercial silver nanopowder, 15 mg of silicon dioxide nanopowder, 120 mg of Nafion ionomer solution, and 3.5 mL of isopropanol were ultrasonically mixed. Ag-TiO<sub>2</sub> catalyst ink was fabricated with same method as for Ag-SiO<sub>2</sub> catalyst ink except for adding TiO<sub>2</sub> instead of SiO<sub>2</sub>. The catalyst ink for Ag black was prepared using the same method as for Ag-SiO<sub>2</sub>, but without the silicon dioxide nanopowder.

### Preparation of Ir-based electrode for anode

The electrode for OER, employed as the anode, was fabricated by spraying catalyst ink onto a platinized titanium screen using a 70 °C hot plate. The catalyst ink was prepared by mixing 120 mg of commercial iridium oxide (Alfa Aesar) with 120 mg of 5 wt% Nafion ionomer solution and 4 mL of isopropanol. The electrode had an area of 10 cm<sup>2</sup>, and the iridium oxide loading was set at 2 mg cm<sup>-2</sup>.

### Single-cell electrochemical CO<sub>2</sub> reduction reaction test

MEAs were fabricated using the catalyst-coated electrode method for electrochemical reactions, and the geometric

electrode area was set at 10 cm<sup>2</sup>. The fabricated electrodes, along with commercial IrO<sub>2</sub>-sprayed platinized titanium screen electrodes (Alfa Aesar, with a target loading of 2.0 mg cm<sup>-2</sup>), were employed as cathodes and anodes in all single-cell tests, respectively. The AEM (Dioxide Materials, X37-50 Grade RT) underwent pretreatment in a 1 M KOH solution for 48 h and was rinsed multiple times with deionized water before use. Following this, a 0.1 M KHCO<sub>3</sub> solution, acting as the electrolyte, was introduced to the anode side *via* a pump. Concurrently, 200 sccm of humidified CO<sub>2</sub> gas at 80 °C, heated using a mantle, was introduced to the cathode side. The electrochemical tests were conducted using a VSP potentiostat (BioLogic, VMP3B-20) equipped with a booster up to 20 A. The CO<sub>2</sub>RR was conducted over 18 min for each applied current density.

A gas chromatograph (GC, Agilent 7890A) was employed for product gas analysis at the GC outlet. A water trap was interposed between the GC and the cathode outlet. Argon gas (99.999%) served as the carrier gas. The GC was fitted with a flame ionization detector (FID) to detect hydrocarbons like CO, CH<sub>4</sub>, and C<sub>2</sub>H<sub>4</sub>, and a thermal conductivity detector (TCD) for hydrogen (H<sub>2</sub>) gas detection. A methanizer was utilized to enhance CO detection before routing to the FID. Measurements of the product gases commenced 9 min after initiation of CO<sub>2</sub>RR for each current density setting. The FE<sub>s</sub> of H<sub>2</sub> and CO were computed using the following equation:

$$\text{FE}_{\text{product}} (\%) = \frac{i_{\text{product}}}{i_{\text{total}}} \times 100 = \frac{V_{\text{product}} \times Q \times \frac{2Fp}{RT}}{i_{\text{total}}} \times 100$$

where  $Q$  = flow rate of the product:  $F$  = faradaic constant (96 485 C mol<sup>-1</sup>):  $p$  = pressure:  $T$  = room temperature (298 K):  $R$  = ideal gas constant (8.314 J mol<sup>-1</sup> K<sup>-1</sup>).

The partial current densities of the products were determined from the volume of a specific product, as indicated by the GC peak.

### Physical characterization

The size distribution and microstructure of the Ag black and Ag-SiO<sub>2</sub> electrodes were examined using high-resolution transmission electron microscopy (HR-TEM, Titan at 300 kV, FEI Co., USA). HR-TEM images, high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) images, and energy-dispersive spectroscopy (EDS) mapping were performed with a Talos F200X system (FEI). Raman spectroscopy was employed to characterize various electrodes, powdered samples, and the prepared solutions, and was conducted at room temperature with a 532-nm laser (Renishaw). XPS (X-ray photoelectron spectroscopy, Nexsa, ThermoFisher Scientific) was conducted with a base pressure of  $2 \times 10^{-8}$  mbar and a monochromated Al K $\alpha$  (1486.6 eV) X-ray source. All XPS spectra were calibrated using the C 1s peak (284.8 eV) as a reference.

### *In situ/operando* Raman spectroscopy

*In situ/operando* SERS (surface-enhanced Raman spectroscopy) was conducted using a standard three-electrode system, a custom-made *in situ* Raman cell (details provided in Fig. S14,

ESI<sup>†</sup>), and a laser with a 532-nm wavelength. The working electrode was fashioned by spraying catalyst ink (containing Ag and Ag-SiO<sub>2</sub> powders) onto a GDL (Sigracet 39BB, SGL Carbon) substrate, which amplified the Raman spectrum signal. A Pt wire and Ag/AgCl (3 M NaCl) served as the counter and reference electrodes, respectively. The electrolyte was either 1 M KHCO<sub>3</sub> or 1 M CsHCO<sub>3</sub>, and gaseous CO<sub>2</sub> was purged onto the working electrode at a flow rate controlled with a ball flow-meter. The electrochemical experiments were controlled using a potentiostat (CompactStat, Ivium Technologies, Eindhoven, Netherlands). The thin electrolyte layer enveloping the electrode facilitated Raman spectroscopic observation of the working electrode's surface.

## Author contributions

C. L., S. K. and J. H. S. designed/conducted the experiments, analyzed the data and wrote the manuscript. M. H. H. performed Raman analysis of Ag black and Ag-SiO<sub>2</sub>. Y.-J. K. contributed to the electrochemical cell tests. K. Y. L. and J. Y. C. provided an idea for the electrochemical analysis. H.-S. O. and W. H. L. supervised the research and wrote the manuscript. All authors reviewed the manuscript.

## Conflicts of interest

There are no conflicts to declare.
