Electrophile-promoted cyclizations of functionalized alkynes offer a useful tool for constructing halogen-substituted heterocycles primed for further derivatization. Preinstallation of an iodo-substituent at the alkyne prior to iodo-cyclization opens access to *ortho* di-iodinated heterocyclic precursors for the preparation of unsymmetrical heterocycle-fused enediynes. This general approach was used to prepare 2,3-diiodobenzothiophene, 2,3-diiodoindole, and 2,3-diiodobenzofuran, a useful family of substrates for systematic studies of the role of heteroatoms on the regioselectivity of cross-coupling reactions. Diiodobenzothiophene showed much higher regioselectivity for Sonogashira cross-coupling at C2 than diiodoindole and diiodobenzofuran. As a result, benzothiophene can be conveniently involved in a one-pot sequential coupling with two different alkynes, yielding unsymmetrical benzothiophene-fused enediynes. On the other hand, the Sonogashira reaction of diiodoindole and diiodobenzofuran formed considerable amounts of di-substituted enediynes in addition to the monoalkyne product by coupling at C2. Interestingly, no C3-monocoupling products were observed for all of the diiodides, suggesting that the incorporation of the 1st alkyne at C2 activates the C3 position for the 2nd coupling. Additional factors affecting regioselectivity were detected, discussed and connected, through computational analysis, to transmetalation being the rate-determining step for the Sonogashira reaction. Several enediynes synthesized showed cytotoxic activity, which is not associated with DNA strand breaks typical of natural enediyne antibiotics.

Introduction

Electrophile-promoted cyclization of functionalized alkynes is a valuable tool for the synthesis of halogen-substituted heterocycles.^{1–7} The reaction is suitable for different nucleophilic functional groups and alkynes. The most recent examples of electrophile-promoted cyclization for “halogen”

electrophiles open access to oxazinoindolones,⁸ 3-sulfonamido-4-haloisocoumarins,⁹ sulfonamido-substituted polyaromatic compounds,¹⁰ medium-sized oxacycles,¹¹ iodofuranones,¹² iodothiazines,¹³ highly distorted fused helicenes^{14,15} and optically active tricyclic piperazine scaffolds through dearomative *ipso*-cyclization.¹⁶ Electrophile-promoted cyclization of various functionalized alkynes has been applied to construct polyheterocycles targeting nucleic acids.¹⁷

Earlier, we have shown that iodocyclization of *ortho*-functionalized aryldiacetylenes followed by the Sonogashira reaction is a convenient approach for the construction of unsymmetrically substituted enediyne systems fused to heteroindenes with the highest yields and functional group tolerance in the case of benzothiophene and indole (Fig. 1A).¹⁸

This “diacetylenic approach” was used in the synthesis of 10-membered heterocyclic analogues of enediyne antibiotics.^{19–22} However, this method has some limitations associated with the possibility of iodination of the second

triple bond in the case of benzofuran and isocoumarin derivatives.^{18,23,24} An alternative way to obtain unsymmetrically substituted enediyne fused to heterocycles could be the regioselective stepwise substitution of different halogens, which has been applied for pyrimidine-fused enediyne (Fig. 1B).²⁵ Here we investigate the applicability of this approach under one-pot conditions for 2,3-diiodoheteroindenes (Fig. 1C).

2,3-Diiodoheteroindenes can be obtained in several ways (Fig. 2). The first method is direct electrophilic iodination which has been applied to indoles,^{26,27} benzothiophene,²⁸ and 2-iodoindole.²⁹ The second approach is based on the sequences of metalation/iodine exchange steps, which has been reported for diiodoindoles.³⁰ All three compounds can also be obtained by iodination decarboxylation techniques, either as the desired products (reported for indoles^{31,32} and benzothiophene³³) or as by-products (reported for benzothiophene and benzofuran,³⁴ albeit without the support of spectral data for 2,3-diiodobenzofuran). The highest yield for diiodobenzothiophene is reachable by the synthesis of a 3-iodo-2-trimethylsilyl derivative followed by the Si-iodine exchange using ICl.^{35,36}

In principle, iodocyclization of *ortho*-functionalized iodoethynylarenes can be considered a convenient alternative synthetic approach towards diiodoheteroindenes (Fig. 1).

Fig. 2 Literature approaches for the synthesis of 2,3-diiodoheteroindenes.

However, to the best of our knowledge, the possibility of using electrophile-promoted cyclizations as a route to diiodoheteroindenes has not been studied, despite the fact that electrophile-promoted cyclization has been used as a synthetic tool for benzo[*b*]thiophenes with different halogen substituents,³⁷ as well as dihalothieno[2,3-*b*]quinoline and dihaloselenopheno[2,3-*b*]quinoline.³⁸

The regioselectivity of the CC cross-coupling reaction is an important problem that is being studied both theoretically and experimentally.³⁹ It is known that the halogen atoms in 2,3-diiodo- and 2,3-dibromothiophenes as well as in 2,3-dibromoindoles have different reactivities in cross-coupling reactions.⁴⁰ Because the C2 position is more reactive than the C3 position, regioselective Sonogashira reactions at the C2 position have been reported for 2,3-dibromothiophene derivatives,^{41–43} 2,3-dibromofuran,⁴³ 2,3-diiodothiophenes,⁴⁴ diiodothienopyridine,⁴⁵ and 2,3-dibromobenzo[*b*]thiophene (Fig. 3).⁴⁶ Even tetrabromothiophene can undergo the regioselective C2,C5 Sonogashira coupling.⁴³ Not surprisingly, the regioselective C2–I Sonogashira coupling has also been shown for C2-iodo/C3-bromo derivatives: 3-bromo-2-iodobenzo[*b*]thio-

Fig. 3 Known regioselectivity for the Sonogashira reaction of dihalothiophenes, furans and heteroindenes.

phene⁴³ and 3-bromo-2-iodoindole,⁴⁷ where the more reactive halogen was placed at an intrinsically more reactive position. In the case of C2-bromo/C3-iodo derivatives, where the above two factors are in conflict, the C2/C3 regioselectivity is reversed. Thus, C3-iodo regioselectivity has been observed for 2-bromo-3-iodothiophenes^{48–51} and 2-bromo-3-iodofuran and -benzofuran.⁵² However, the selectivity of cross-coupling in 2,3-diiodoheteroindenes (benzo[*b*]thiophene, indole, and benzo[*b*]furan) has not been previously studied. 2,3-Diiodoindoles were only used in the synthesis of symmetrical diethynylindoles.⁵³

In this work, we report on the study of electrophile-promoted cyclization of functionalized iodoethynylarenes and the investigation of the regioselectivity of the Sonogashira reaction for 2,3-diiodoheteroindenes for the development of a new “iodoalkyne” approach towards unsymmetrically substituted enediynes fused to heteroindenes (Fig. 1).

Scheme 1 Synthesis of *o*-functionalized (iodoethynyl)arenes **3a–c**.

Results and discussion

Study on the electrophile-promoted cyclization of iodoalkynes

The starting 2-(iodoethynyl) derivatives of thioanisole **3a**, *N,N*-dimethylaniline **3b** and anisole **3c** were obtained from the corresponding TMS-alkynes **1a–c** (see the ESI†) by a stepwise desilylation and iodination of terminal alkynes **2a–c** (Scheme 1).

Iodoalkynes **3a–c** turned out to be quite sensitive substances. They require mild reaction conditions and should be handled carefully during workup and isolation in order to avoid protodeiodination (see the ESI†). Thus, the iodoalkynes should not be stored in solution for a prolonged time and the water bath temperature for a rotary evaporator should not exceed 35 °C. With these rules, the key iodoalkynes **3a–c** could be obtained in high yields (Scheme 1) and neatly stored in a freezer for several months without any degradation.

Then, we turned our attention towards the study of iodocyclization of iodoalkynes **3a–c** under reaction conditions, which gave the highest yields in the case of alkyl-/aryl-substituted *ortho*-functionalized alkynes.^{54–56} (Iodoethynyl)thioanisole **3a** underwent the iodocyclization smoothly with iodine as an electrophile: 2,3-diiodobenzo[*b*]thiophene **4** was isolated in an almost quantitative yield (Table 1, entry 1). The cyclization of aniline **3b** using iodine gave a complex mixture of products. Switching to *N*-iodosuccinimide gave indole **5** in 86% yield (Table 1, entry 2). The reaction of anisole **3c** with either iodine (under a variety of conditions) or ICl ended with electrophilic addition to the triple bond to form dihalogenated alkenes **6** and **7**, respectively (Table 1, entries 3 and 4). When NIS was used, no conversion of the starting (iodoethynyl)anisole was observed even after 6 hours (Table 1, entry 5). However, we could overcome this obstacle using 2-ethynylated phenols instead of anisoles and by switching to NIS/ PPH_3 as the electrophilic system as described previously by Li *et al.*⁵⁷

Interestingly, when optimizing the synthesis of (iodoethynyl)phenol **3d**, we inadvertently found that desilylation/iodina-

tion of TMS-substituted ethynylphenol **1d** under AgF/NIS conditions⁵⁸ gave the desired 2,3-diiodobenzofuran **8**, albeit in a low yield (13%) and along with a mixture of unidentified products. Iodocyclization of (iodoethynyl)phenol **3d** under NIS/PPh₃ conditions gave 2,3-diiodobenzofuran **8** in 37% isolated yield (Scheme 2).

Thus, the preinstallation of iodine at the triple bond of *ortho*-functionalized ethynylarenes enables direct synthesis of 2,3-diiodobenzothiophene and 2,3-diiodoindole. Although iodination of 2-(iodoethynyl)anisole leads instead to the 1,2-diiodination of the triple bond, the target 2,3-diiodobenzofuran can be synthesized using 2-(iodoethynyl)phenol as a starting material and the NIS/PPh₃ system as the electrophilic reagent.

Regioselectivity of the Sonogashira coupling in 2,3-diiodoheteroindenes

Next, we explored the regioselectivity of the Sonogashira coupling^{59,60} for diiodides **4**, **5**, and **8**. The idea of selective substitution of one iodine atom in vicinal diiodoheteroindenes is based on the known regioselective Sonogashira reaction for 2,3-diiodothiophenes⁴⁴ and 2,3-dibromobenzo[*b*]thiophene.⁴⁶ The substitution is known to occur first at C2, and then at the C3 position.

From the theoretical point of view, many factors influence the regioselectivity of the oxidative addition step, which is known to be the limiting stage of many Pd cross-coupling reactions.³⁹ An interesting selectivity feature is that the reaction does not prefer the *weaker* two C–X bonds as indicated by the data shown in Fig. 4 for C–Br and C–I bonds in the two dihalides. Interestingly, the shorter and stronger C2–Hal bonds react first. Such observations are consistent with the earlier

suggestion that the rate-limiting step for the Sonogashira cross-coupling of aryl iodides is likely to be not the C–X bond activation *via* oxidative addition to the catalyst but *trans*-metalation of Cu-acetylides formed in the initial reaction stage.⁶¹

Therefore, we aimed to experimentally compare the regioselectivity of the cross-coupling for all three diiodoheteroindenes **4**, **5**, and **8** with the goal of evaluating how general the above trend is. From a practical point of view, this information is useful for deciding which heterocycles are appropriate for the synthesis of unsymmetrical enediyne systems under one-pot conditions.

To study the regioselectivity in the Sonogashira reaction of diiodobenzothiophene **4**, we chose 3-methoxypropyne **9a** as a partner because its regioselective cross-coupling would lead to the corresponding C2-(methoxymethyl)ethynyl derivative, which is an important starting material for the synthesis of cyclic enediyne systems through the Nicholas reaction (Table 2).¹⁹

All reactions were carried out using a Pd(PPh₃)₄/CuI catalytic system, while the nature of the base, solvent, temperature and reagent ratio was varied. The yields of all products and the conversion of diiodide **4** were estimated using ¹H NMR spectroscopy of the reaction mixture with 1,3,5-trimethoxybenzene as the internal standard. The Sonogashira coupling of diiodide **4** with alkyne **9a** using potassium carbonate as a base at 45 °C gave C2-monosubstituted product **10a** in 76% yield. However, a non-desired disubstituted product **11a** was also formed in 11% yield (Table 2, entry 1). Raising the temperature from 45 °C to 60 °C decreased the yield of monoethynylated benzo[*b*]thiophene **10a** (Table 2, entry 2). Among the various bases tested (Table 2, entries 3–5), the best result was achieved with K₃PO₄ (80% yield of **10a**, entry 3), albeit with the concomitant formation of 9% of enediyne **11a**. In order to diminish the formation of undesired enediyne **11a**, we reduced the acetylene/

^a Reaction conditions: **4** (0.25 mmol, 1 equiv.), **9a** (0.30 mmol, 1.2 equiv.), Pd(PPh₃)₄ (5 mol%), CuI (10 mol%), base (1.00 mmol, 4.00 equiv.), THF (2.50 mL, *c* = 0.1 M), 24 h. ^b Conversion and yield were determined by ¹H NMR spectroscopy using 1,3,5-trimethoxybenzene as an internal standard. ^c DMF was used as a solvent. ^d Alkyne **9a** was used in an amount of 0.25 mmol, 1.00 equiv.

diiodide ratio from 1.2 to 1.0 equiv. (Table 2, entry 6) but found that these conditions led to a decrease in the yield of product **10a**. Thus, the conditions from entry 3 were chosen for the regioselective synthesis of 2-ethynyl-3-iodobenzothiophene **10a**: the reaction should be carried out in THF at 45 °C using K_3PO_4 as a base and maintaining the starting diiodide **4** to alkyne **9a** ratio of 1 : 1.25.

Importantly, the product of monosubstitution at C3 has never been observed. Thus, the ethynyl substituent at the C2-position of benzothiophene has an activating effect on the rate of cross-coupling at the C3 position. This activation can be associated either with a decrease in electron density at the C3 position for 2-ethynyl-3-iodobenzothiophenes compared to 2,3-diiodobenzothiophene because of the electron-withdrawing properties of Csp atoms, or/and with other factors such as coordination of palladium at the triple bond in the oxidative addition step.

Studies on the regioselectivity of indole **5** and benzofuran **8** derivatives were carried out under optimized conditions for diiodobenzothiophene **4**. We found that 2,3-diiodoindole **5** cannot be converted to the corresponding C2-ethynylindoles with the same selectivity as it was observed for 2,3-diiodobenzothiophene **4** (Scheme 3). Although the desired C2-ethynylated indole **13a** was the main reaction product (52% yield) of the Sonogashira reaction with alkyne **9a** (Scheme 11), enediyne **14a** (18%) along with the remaining starting diiodide **5** (87% conversion) was also isolated. Raising the temperature by 10°C led to the increased formation of symmetrically substituted enediyne **14a**, with starting diiodide **5** still present in the reaction mixture.

The Sonogashira coupling of benzofuran diiodide **8** with methyl propargyl ether **9a** proceeded mostly through the C2-position with similar regioselectivity to diiodoindole **5** of 2/1, with the isolated yields of 59% for 2-ethynylbenzofuran **15a** and 27% for enediyne **16**.

Moderate yields and less selectivity for monoethynylation in the case of indole **5** and benzofuran **8** compared to benzothiophene **4** against the formation of the diethynylated byproduct can be explained by higher sensitivity of the C3-I position towards additional activation by the initially introduced C2-alkyne moiety for these heterocycles.

Finally, we decided to check the possibility of reversing the regioselectivity for the benzothiophene series from C2-I to C3-I by replacing active halogen (I) with less reactive halogen (Br) at a more activated position (C2). Thus, the corresponding C3-I regioselective Sonogashira reaction has been reported for

Scheme 3 Study of the regioselectivity of the Sonogashira reaction for 2,3-diiodoindole **5** and 2,3-diiodobenzofuran **8**.

2-bromo-3-iodothiophenes (Fig. 3).^{48–51} 2-Bromo-3-iodobenzothiophene **17** was obtained similarly to its diiodide analogue **4** starting from bromoethynylthioanisole **S1** (see the ESI†). The Sonogashira reaction of 2-bromo-3-iodobenzothiophene **17** with 3-methoxypropyne **9a** under optimized conditions for diiodobenzothiophene **4** (Table 2, entry 3) proceeded at the C3-I bond instead of the C2-Br bond. However, the selectivity for the mono- vs. bis-substitution was significantly lower than the C2-selectivity observed for substitution to diiodide **4**. Along with the iodine substitution at the C3 position (product **18a**), a significant amount of the disubstituted benzothiophene **11a** was formed: the ratio of alkyne **18a** to enediyne **11a** was found to be 2 : 1 (Scheme 4). It should be noted that the C2-Br substitution in the starting material was not observed, so the difference in the intrinsic reactivity of C-Br and C-I bonds was more important than the inherent C2 preference. It also indicates once again that even for the C2-Br benzothiophene derivative, a triple bond has an activation effect at the adjacent position.

Additional selectivity studies of dihalobenzothiophenes

To explore the activating influence of the firstly introduced triple bond on the remaining C-Hal in the Sonogashira coupling, we carried out additional experiments. In particular, we studied interactions of the two dihaloheteroindenes with the worst mono- vs. bis-ethynylation selectivity (*i.e.*, **8** and **17**) with hept-1-yne **9b**, an alkyne without any additional functionalities (Scheme 5).

In the case of di-I-benzofuran **8**, the mono- to bis-ethynylation ratio increased from 2/1 (for methyl propargyl ether **9a**) to 4/1 (for hept-1-yne **9b**).

Scheme 4 Study of the regioselectivity of the Sonogashira reaction for 2-bromo-3-iodobenzothiophenes **17**.

Scheme 5 Study of the influence of the alkyne nature on mono- vs. bis-ethynylation selectivity.

An analogous trend was observed for C2-bromo benzothio-
phene **17**: the mono-**18b** to bis-ethynylation **11b** ratio also
increased from 2/1 (for methyl propargyl ether **9a**) to 3/1 (for
heptyne **9b**) (Scheme 5). The results are intriguing because the
first alkyne is introduced at different carbons (C2 for **8** and C3
for **17**) in these Sonogashira reactions.

Exploratory computational analysis

Several interesting observations can be made from the experi-
mental results discussed in the previous sections. First, the
introduction of the first alkyne group accelerates the 2nd ethy-
nylation step. Second, the activation effect of the firstly incor-
porated triple bond is dependent on the alkyne substituent,
i.e., the acceleration is less pronounced for heptyne **9b** in com-
parison to that of methyl propargyl ether **9a**.

In order to understand the electronic consequences of
alkyne introduction, we used DFT calculations to evaluate
charge distribution in 2,3-diiodobenzothiophene **4** and the
two products of Sonogashira mono-substitution at C2 –
2-ethynyl-3-iodobenzothiophenes **10a** and **10b'** (Scheme 6). At
this stage, we limited our computational analysis only to the
benzothiophene systems where the experimental data are the
most complete. Note that the C2-carbon in the starting diio-
dide **4** has much more electron density than C3 (natural
charges of -0.48 and $-0.30e$). Upon the introduction of C2-
alkyne substituents, the electron density at both C2 and C3 is
significantly lowered. This interesting finding illustrates the
uniqueness of sp-hybridized carbon and is consistent with the
high acceptor ability of alkynes.^{62,63}

The introduction of an oxygen atom at the propargylic posi-
tion further decreases electron density at the C3 atom. This
effect stems from a combination of the inductive effect and
 $\pi_{C\equiv C} \rightarrow \sigma^*_{CO}$ hyperconjugation, both of which accentuate the
 π accepting ability of the sp carbon. If this remote stereoelec-
tronic effect can facilitate a reaction at the remaining C–Hal
bond, it can explain the lower mono- *vs.* bis-ethynylation
selectivity for the propargylic ether.

As transmetallation is known to be the rate-limiting step in
Sonogashira reactions of aryl iodides,^{64,65} we evaluated substi-
tuent effects on this step with the hope that they will help to

Scheme 6 The activating effect of the alkyne moiety and $\pi_{C\equiv C} \rightarrow \sigma^*_{CO}$ hyperconjugation on the C3 carbon in benzothiophenes.

explain the observed reactivity trends. Scheme 7 illustrates the
differences in the calculated exergonicities for transmetalla-
tion. In this context, it is important to remember that, as long
as the same elementary processes are compared, exergonicities
are known to correlate with activation barriers. Such a connec-
tion between reaction thermodynamics and kinetics readily
follows from the Marcus theory or the Bell–Evans–Polanyi
postulate.^{66,67} For more recent examples of such connections
between kinetics and thermodynamics, see ref. 68 and 69.

The results of these calculations provided three con-
clusions, all in good agreement with the experimental results.
In particular, a comparison of eqn (1) and (2) explains the pre-
ference for the reaction at C2 as this process is more favorable.
The more exergonic transmetalation at C2 (-19.4 kcal mol⁻¹)
is expected to be faster than the less exergonic reaction at C3
(-17.8 kcal mol⁻¹). On the other hand, a comparison of eqn
(2) and (3) rationalizes the accelerating effect of the alkyne
moiety which complicates reaction designs that rely on the
selective formation of mono-alkynylated Sonogashira products
from the diiodides. Finally, a comparison of eqn (3) and (4)
shows how the propargylic acceptor group at C2 further pro-
motes transmetalation at C3, rendering selective monoalkyny-
lation even more difficult.

Preparation of non-symmetric enediynes

Next, we applied the optimized conditions to the Sonogashira
cross-coupling of diiodide **4** with different alkynes **9a–f**
(Scheme 8). In all cases, the reaction proceeded with the full
conversion of diiodide **4** and gave 2-ethynyl-3-iodobenzothioph-
enes **10a–e** in good isolated yields.

The enediyne by-products were formed in insignificant
amounts; therefore, they were not isolated chromatographi-
cally. Consequently, 2,3-diiodobenzothiophene shows minimal
dependence of regioselectivity on the nature of the alkyne.

In order to demonstrate the utility of the regioselective
Sonogashira reactions, we carried out a two-step synthesis of
unsymmetrically substituted enediyne systems from 2,3-diio-

Scheme 7 Thermodynamics of transmetalations in relevant benzothiophenes.

Scheme 8 Synthesis of 2-ethynylbenzo[b]thiophenes **10a–f**.

dobenzothiophene **4** via two successive cross-coupling reactions with different alkynes under one-pot conditions, *i.e.*, without isolating the product of the first Sonogashira reaction

on the C2 atom. It turned out that this approach allowed quick and efficient preparation of the unsymmetrically substituted enediynes **19a–e**. In this sequence, the first substitution at C2 was carried out under the optimized conditions (Table 1, entry 3), while the subsequent C3-substitution of iodine was accomplished by adding the second alkyne to the reaction mixture and running the reaction at 60 °C until the complete conversion. In this way, it was possible to obtain a series of unsymmetrically substituted enediynes, including isomeric enediynes **19a/19b** and **19c/19d** (Scheme 9). Because the resulting enediynes have substituents with different polarity at the triple bonds, chromatographic separation of the target unsymmetrical enediynes **19** from symmetrically substituted by-products **11a** and **b** is straightforward. The isolation of the trace amounts of symmetrical enediyne minor by-products in the syntheses of compounds **19c–e** was not carried out.

Thus, unsymmetrically substituted enediynes fused to benzo[b]thiophene **19** can be synthesized from the easily synthetically accessible 2,3-diiodobenzo[b]thiophene **4** within a single synthetic stage using a one-pot procedure involving two subsequent Sonogashira reactions. The advantage of the developed synthetic route compared to the previously described approach based on the iodocyclization of *o*-(buta-1,3-diyne) thioanisole followed by the Pd-catalyzed cross-coupling with alkynes is its higher divergence without the need to start from different diacetylenes in the first synthetic steps.

We have compared the overall yield of enediyne **19a** synthesized by two different routes – through the “diacetylenic” approach^{19,24} and via the “iodoalkyne” approach (Scheme 10). The new method gives a somewhat higher overall yield;

Scheme 9 Synthesis of unsymmetrically substituted enediynes **19** using a one-pot approach.

Scheme 10 Comparison of the efficiency of the “diacetylenic” and the “iodoalkyne” routes towards acyclic enediynes fused to benzothiophene. The two routes are defined in Scheme 1.

however, it still requires separating traces of symmetrical enediynes in the last step. Therefore, we would recommend using the developed “iodoalkyne” approach for the synthesis of libraries of unsymmetrical benzothiophene-fused enediynes, while the “diacetylenic” route seems to be more suitable for the gram-scale synthesis of enediynes with an identically substituted triple bond at the C2 position.²²

Preparation of symmetric enediynes

The symmetrically substituted enediynes can be synthesized directly from diiodides **4**, **5**, and **8** by the Sonogashira coupling at 60 °C. Following this way, several enediynes fused to benzothiophenes **11a–d**, indole **14a**, and benzofuran **16a** were synthesized mostly in good yields (Scheme 11).

Biological activity of acyclic enediynes

It has recently been shown that several acyclic $\text{C}_6\text{F}_5\text{S(O)}$ -substituted enediynes exhibit cytotoxic activity unrelated to the Bergman cyclization. It is assumed that cytotoxicity is associated with the disruption of the microtubule network.⁷⁰ Although the presence of a pentafluoroaryl moiety was thought to be responsible for the binding of enediynes to tubulin through nucleophilic aromatic substitution, an enediyne molecule lacking this group was also active against human pancreatic tumor cells MIAPaCa-2 ($\text{IC}_{50} = 15.9 \mu\text{M}$). Furthermore, we have independently demonstrated that dialkylaminomethyl-substituted benzothiophene-fused acyclic enediynes show cytotoxic activity against NCI-H460 lung carcinoma.⁷¹

Therefore, we decided to test cytotoxicity for a series of acyclic enediynes fused to benzothiophene and indole. The list of compounds included enediynes **11a–d** and **19a–e** obtained in this work, as well as enediynes **19f–h**,²² **19i** and **j** (see the ESI[†]), and **20**²⁴ synthesized in our group earlier using the “diacetylenic” route. The cytotoxicity of these compounds was tested against NCI-H460 lung carcinoma and WI-26 VA4 lung epithelial-like cell lines using the MTT colorimetric test.^{72,73} All the enediynes were studied at a concentration of 75 μM . Most of the unsymmetrically substituted enediynes fused to benzothiophene **19** and an indole derivative **20** showed cytotoxic activity against NCI-H460 lung carcinoma cells. Furthermore, enediynes **19b**, **c**, **g**, and **h**, and **20** were more cytotoxic towards the NCI-H460 cells than to WI-26 VA4 lung epithelial-like fibroblasts (Fig. 5).

Scheme 11 Synthesis of symmetrically substituted enediynes fused to benzothiophenes **11a–d**, indole **14a** and benzofuran **16a**.

Earlier, the Hu group showed that acyclic enediynes having a double bond as a part of a maleimide ring and with a σ -acceptor atom at the propargylic position are able to undergo MARACA transformation (a cascade acetylene–allene isomeri-

Fig. 5 Screening for the cytotoxicity of the enediynes fused to benzothiophenes **11** and **19** and indole **20**.

zation) under polar conditions. This reaction cascade leads to enyne allenes, prone to the formation of reactive σ,π -diradicals through the Myers–Saito cyclization that induce DNA breaks.^{74,75} Taking into account that most of the enediynes tested here have a propargylic σ -acceptor, we decided to check the ability of the acyclic enediynes to induce DNA strand breaks. Enediynes **19a–c**, **f**, **i**, and **j**, and **20** were chosen and investigated in the assay with a pBR322 DNA plasmid under the same conditions as those for cyclic analogs of benzothiophene-fused enediynes.²⁰ The obtained data revealed that only enediyne **19i** possessed a weak DNA damaging activity: a trace amount of open circular DNA was detected in the electropherogram (Fig. 6). Other enediynes did not show DNA damaging activity. This finding confirms that the cytotoxicity of acyclic enediynes studied here is associated neither with the Bergman cyclization nor with the Myers–Saito cyclization. It may be worth noting that enediynes can also form polar intermediates that can also damage biomolecules.⁷⁶

Therefore, revealing the mechanism of the cytotoxicity of enediynes requires further studies.

Conclusions

In summary, the iodocyclization of *ortho*-functionalized (iodoethynyl)arenes along with the regioselective Sonogashira coupling opens a convenient synthetic route towards heteroindene-fused unsymmetrical enediynes. 2,3-Diiodobenzothiophene and 2,3-diiodoindole were easily accessible *via* iodocyclization. Although (iodoethynyl)anisole underwent iodination of the triple bond instead of cyclization, 2,3-diiodobenzofuran could be prepared, instead, from (iodoethynyl)phenol and NIS/ PPh_3 .

The regioselective outcome of the Sonogashira reaction for 2,3-diiodoheteroindenes depends on the nature of the heterocycle, as well as on the nature of alkynes. The Sonogashira coupling for all derivatives follows the C2-regioselectivity rule, without producing a C3 mono-substitution byproduct. However, the regioselectivity suffers from the activating influence of the initially introduced alkyne on the adjacent C–Hal position, resulting in the formation of a disubstituted byproduct. This effect is stronger for diiodoindole and diiodobenzofuran than for diiodobenzothiophene. The ratio of mono- and disubstituted products also depends on the nature of the alkyne. Alkynes with propargylic acceptors at C2 have a greater activating effect at the C3 position towards the subsequent Sonogashira reaction.

Fig. 6 Electropherogram of the pBR322 plasmid after exposure to 250 μ M concentrations of enediynes **19a–c**, **f**, **i**, and **j**, and **20**. CC – covalently closed circular plasmid; OC – open circular form.

As a result, diethynylation does not preclude the synthesis of unsymmetrical benzothiophene-fused enediynes based on a sequential one-pot C2/C3 ethynylation, but limits the use of the one-pot approach for the indole and benzofuran derivatives. In this case, either the “diacetylene” route or the step-wise two-pot substitution of both iodine atoms by the Sonogashira cross-coupling is recommended.

In addition, these experimental selectivity trends provided a tool to probe the mechanistic features of the Sonogashira cross-coupling. A diverse set of DFT data, including C–X bond strength, C–X bond polarizations, electron density distributions, and reaction exergonicities converge on transmetalation, rather than oxidative addition, as the rate-limiting step of this reaction cascade. Computational analysis using various levels of DFT revealed a few significant points about the selectivity and provided insight into the mechanistic basis of the observed selectivities in the Sonogashira coupling.

Importantly, the alkyne moiety is an activating substituent (more than the heavier halogens). Furthermore, a remote (propargylic) acceptor can make this activating effect more pronounced. This observation illustrates once again the unique properties of the alkyne functionality – it is both a significantly electronegative substituent and a perfect conduit for stereo-electronic hyperconjugative effects.⁷⁷

The acyclic unsymmetrical enediynes showed cytotoxic activity against NCI-H460 lung carcinoma cell lines along with lower cytotoxicity toward WI-26 VA4 lung epithelial-like cell lines. Interestingly, the mechanism of the cytotoxicity is not associated with the induction of DNA strand breaks.
