This is an Accepted Manuscript, which has been through the RSC Publishing peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, which is prior to technical editing, formatting and proof reading. This free service from RSC Publishing allows authors to make their results available to the community, in citable form, before publication of the edited article. This Accepted Manuscript will be replaced by the edited and formatted Advance Article as soon as this is available.

To cite this manuscript please use its permanent Digital Object Identifier (DOI®), which is identical for all formats of publication.

More information about Accepted Manuscripts can be found in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics contained in the manuscript submitted by the author(s) which may alter content, and that the standard Terms & Conditions and the ethical guidelines that apply to the journal are still applicable. In no event shall the RSC be held responsible for any errors or omissions in these Accepted Manuscript manuscripts or any consequences arising from the use of any information contained in them.
Synthesis of Polymeric Ladders by Topochemical Polymerization

Xiaodong Hou, Zhihan Wang, Joseph Lee, Erin Wysocki, Casey Oian, Jennifer Schlak, and Qianli Chu*

DOI: 10.1039/b000000x

Two polymeric ladders were synthesized by topochemical polymerization. The critical assemblies with multiple reactive centers were characterized by single crystal X-ray diffraction. Approximately 64% and 70% of the mass of the two polymeric ladders can be derived from biomass, respectively.

Polymeric ladders are a high value synthetic target and are predicted to have high thermal/chemical stability because the chains do not automatically fall apart if one covalent bond is broken.1,2 Polymeric ladders are constructed with monomers containing more than two reactive centers. The challenge lies in synthesizing a polymeric ladder by the classical one-pot approach because of the potential for cross linking between the monomers. Herein, we report two polymeric ladders synthesized by using topochemical polymerization.3-8

A monomer used in this study is compound 1 with two reactive diene groups connected by an unreactive 1,4-phenylene diester linker (Scheme 1). Facile synthesis of monomer 1 was accomplished in 90% yield by activating sorbic acid with thionyl chloride and then coupling with hydroquinone.

A variety of physical properties were studied to determine if compound 1 is a viable candidate for polymerization. It was found to be a reactive white powder with melting point of 178-180 °C. The differential scanning calorimetry curve (DSC, Fig. 1) showed an endothermic peak at around 179 °C corresponding to its melting point. The exothermic peak to the right of the endothermic peak was consistent with an exothermic event. The featureless curves of first cooling and second heating were also consistent with the completion of the polymerization event. The featureless curves of first cooling and second heating were also consistent with the completion of the polymerization event. The featureless curves of first cooling and second heating were also consistent with the completion of the polymerization event.

To further investigate the solid state polymerization, high quality crystals of monomer 1 were obtained by slowly cooling a saturated DMSO or acetone solution. The structure was determined by single crystal X-ray diffraction. The monomer 1 self-assembled into columnar complexes based on π-π stacking as shown in Fig. 2. Within the assembly, the closest reactive atoms are the 1st diene carbon and 4th diene carbon in the nearest neighboring monomer as marked in Scheme 1 and Fig. 2a. These two adjacent reactive sp2 hybridized carbons are only separated from each other by 3.66 Å and their π orbitals are well overlapping each other. The distance and orientation are ideal to form a new carbon-carbon bond in the solid state upon UV irradiation or heating.9,10 The powder XRD pattern of the synthesized monomer 1 without further processing was nearly identical to that of the calculated one from the single crystals (see ESI) making this crystal structure suitable to analyze and interpret the solid state polymerization for both crystals and powder. After the photopolymerization, the polymer maintained its crystallinity. The powder XRD pattern of the polymer was similar to that of the monomer 1; therefore consistent with the theory that the solid-state polymerization was a topochemical reaction involving minimum movements of the atoms.

Due to the preorganization of the reactive centers in the self-assembly, the monomer 1 is photoreactive allowing each monomer in close enough proximity to react with its two nearest neighbors.
Topochemical reactions offer a unique opportunity to synthesize molecules and macromolecules with regio- and stereo-specificity. Because the topochemical polymerization proceeds with minimum movement of atoms, stereoregular polymeric ladders are proposed as products (Fig. 4). The four carbon-carbon bonds that each monomer forms with its two adjacent neighbors are more than 5 Å away, so the alkenes between self-assemblies are unlikely to react (Fig. 3c). Although the packing of these π-π stacking of the monomer II is different from that of the monomer I (Fig. 2c and 3c), the solid-state reactivity of monomer II is comparable to that of the monomer I. The topochemical UV polymerization of monomer II was finished in the solid state within 64 h at 70 °C, below its melting point 107-108 °C.

To explore the scope of the reaction, monomer II was synthesized (Scheme 2). Specifically, a Knoevenagel condensation between leaf aldehyde and malonic acid followed by a decarboxylation at 60 °C yielded the (2E,4E)-octa-2,4-dienioic acid. This dienoic acid was then activated by thionyl chloride and coupled with hydroquinone to offer the desired monomer II. The formation of the polymeric ladder was confirmed by solid state 13C NMR, which showed the disappearance of two sp² hybridized carbons of the diene concurrent with the appearance of two sp³ hybridized carbons around 43.6 and 56.4 ppm. Hydrolysis of the polymeric product of I yielded hydroquinone and no unreacted monomer was observed by NMR (see ESI). The result of product hydrolysis further supports completion of the topochemical reaction and the formation of the molecular ladder.

Due to the presence of the two three-carbon alkyl chains, the above monomer II has improved solubility in many organic solvents such as acetone, acetonitrile and ethyl acetate when compared with monomer I. X-ray quality crystals of monomer II were obtained by slow evaporation of an acetone solution. The structure determined by single crystal X-ray diffraction is shown in Fig. 3. The critical π-π stacking of the monomer remained in this crystal structure. The distances between the centroids of the aromatic rings shown in the π-π stacking columns in Fig. 2b and 3b are 5.60 and 5.49 Å, respectively. The 1st diene carbon and 4th diene carbon in the adjacent monomers are only 3.62 Å from each other. The closest reactive sp² carbons between self-assemblies are more than 5 Å away, so the alkenes between self-assemblies are unlikely to react (Fig. 3c). Although the packing of these π-π stacking of monomer II is different from that of the monomer I (Fig. 2c and 3c), the solid-state reactivity of monomer II is comparable to that of the monomer I. The topochemical UV polymerization of monomer II was finished in the solid state within 64 h at 70 °C, below its melting point 107-108 °C.

Topochemical reactions offer a unique opportunity to synthesize molecules and macromolecules with regio- and stereo-specificity.9-13 Because the topochemical polymerization proceeds with minimum movement of atoms, stereoregular polymeric ladders are proposed as products (Fig. 4). The four carbon-carbon bonds that each monomer forms with its two adjacent neighbors all involve chiral centers that are generated stereo-specifically. Besides their stereoregularity, the two polymeric ladders have shown excellent chemical stability, which is also important for future applications. They are insoluble in all the common organic solvents. The ladders can tolerate strong acids such as concentrated HCl and TFA, and organic bases such as Et₃N (even when refluxed overnight). However, these ladder polymers are degradable in aqueous potassium hydroxide and can be oxidized by concentrated sulfuric acid.
Another significant characteristic of the polymeric ladders is their partial environmentally friendly origin. The polymeric ladder I is approximately 64% by mass from the renewable starting material sorbic acid. Sorbic acid is commercially available and can be produced from triacetic acid lactone, which is a versatile biorenewable molecule with potential to be a platform chemical for the production of commercially valuable chemical intermediates and end products. The polymeric ladder II is approximately 70% by mass renewable but synthesized from leaf aldehyde and malonic acid. Both chemicals are commercially available and malonic acid can be made from 3-hydroxypropionic acid, which is one of the top sugar-derived building blocks.

In summary, two stereoregular polymeric ladders were synthesized from plant-derived materials. Other starting materials and reagents or their preparations were also readily available and inexpensive. The monomer powder I directly obtained from synthesis was not an amorphous solid, but was indeed microcrystals, which were suitable for topochemical polymerization. The above characters show possibility to scale up the synthesis. The two ladders in this communication align well with a known supramolecular ladder, which was synthesized from a two-dimensional \( p \)-xylelenediammonium discorbate, showing that the topochemical 1,4-polymerization of diene could be a useful reaction to make interesting targets with potential applications. Furthermore, the polymeric ladders exemplified herein will provide an access to other covalently bonded ladder materials, and allow researchers to further explore their unique properties such as mechanical strength.

This work was supported by the Doctoral New Investigator grants of the American Chemical Society Petroleum Research Fund (PRF 52705-DN17) and the National Science Foundation ND EPSCoR program (EPS-0814442). The authors thank Dr. Jeffrey Simpson at MIT for solid state NMR and Dr. Angel Ugrinov at NDSU for powder XRD.
