This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
A mild, efficient and ambient temperature photochemical approach for the synthesis of silver nanoparticle core-shell structures employing a zwitterionic polymer as well as polyethylene glycol is presented.

Polymer nanocomposites have attracted significant interest in recent years due to their unique properties and broad range of potential applications. Silver polymeric nanoparticles (Ag NPs) are particularly sought after due to the combination of their optical, catalytic and antimicrobial properties. However, bare Ag NPs are so far only of limited use in the biomedical and biosensing field since contact with the biological media results in fouling causing either loss of colloidal stability or opsonization. In order to prevent such processes, the Ag NPs must be coated with polymers able to prevent the fouling while concomitantly endowing specific functions. By fusing the properties of Ag NPs with a corona of antifouling polymers, a plethora of new application are accessible. In this context, it is necessary to prepare stable and biocompatible NPs with well-defined surface coatings. Several methods have been employed to prepare polymer functionalized metallic NP such as embedment in a polymer matrix or surface coating to form core-shell structures. The latter is particularly interesting as it results in smaller, well defined nanostructures with significant biomedical potential.

Such core shell structures can be prepared either via a one pot strategy using monomers or the polymer as the reducing/stabilizing agent. Alternatively, a grafting-from approach may be employed, which usually results in heterogenous particles and ill-defined polymer brushes. Mercapto-functional polymers have been extensively used for the functionalization of Au NPs. However, such composites exhibit poor stability and are prone to ligand exchange with thiol-containing molecules present in reaction buffers or cell media.

With the rapid advances in nanoparticle functionalization, various thermally driven methods are often employed for attaching molecular species to the nanoparticles surface. Core shell polymer NPs have mainly been prepared using gold (Au) NP as core nanocomposites via thermally activated chemical strategies. For instance, Peng and co-workers demonstrated coupling of alkyne-terminated poly(N-isopropylacrylamide) to azide-functionalized Au NPs through a copper-catalyzed Huisgen cycloaddition to form thermoresponsive core-shell Au NPs with high grafting densities. In another approach, Beyer et al. employed Diels-Alder chemistry to afford a reversible surface functionalization of Au NPs with poly(styrene), and Aldeek et al. prepared highly fluorescent PEG and zwitterion functionalized Au nanoclusters. There are only limited examples of Ag NP-polymer composites usually containing a poly(ethylene glycol) (PEG) shell. In addition, the current thermally triggered chemical strategies involve the use of additional reagents or catalysts, sensitive functional groups, extensive reaction times (up to several days), the use of elevated temperatures or a combination of all of these, which can impair the NP stability and induce their aggregation.

To overcome the disadvantages associated with thermally controlled reactions, we herein apply a novel light triggered strategy first described by Barner-Kowollik and coworkers to prepare AgNP-polymer core shell NPs using functional polymers. Here, a photocative group based on ortho-quinodimethane (caged diene) is allowed to react with dienophiles such as maleimide groups under UV irradiation (Fig. 1). Light has already been employed for the preparation of tailored nanomaterials however herein a first example for the use of a light triggered

**Figure 1.** Light induced functionalization of Ag NPs with polymers. The novel photoactivatable linker 1 and the inert linker 2 are attached to the Ag NP surface. 1 enables the light-induced cycloaddition with either PEG-Mal 3 or pCBMA 4 upon UV-irradiation resulting in cycloadduct 5.
cycoaddition for the mild, efficient, fast and catalyst free Ag NP modification with antifouling and biocompatible polymers (i.e. poly(carboxylbetaine methacrylate) (pCBMA) and poly(ethylene glycol) (PEG)) enabling temporal reaction control, is presented. PEG is one of the most widely used water soluble, biocompatible polymers, which can enhance the stability of NPs in aqueous solutions or cell media. Zwitterionic pCBMA, on the other hand, outperforms PEG in terms of resistance to non-specific protein adsorption from blood serum and plasma as well as marine fouling and bacteria. In addition, the in situ generation of AgNPs inside betaine brushes has already been exploited as effective antibacterial interface.

Initially, a novel bifunctional linker 1 containing benzotriazole (BT) as the Ag NP anchoring group and a caged diene (photoenol) moiety for light-induced cycloaddition was prepared (Fig. 1). Benzotriazoles have previously been shown to bind strongly to Ag surfaces and have been employed for the modification of Ag NPs. To assess the reactivity of the linker, a model reaction between BT-photoenol 1 and maleimide functionalized PEG 3 (Mn ~ 1300 g·mol⁻¹) was carried out (Fig 2a). Low molecular weight maleimide-PEG was chosen due to its excellent dienophile reactivity and the ease of precise ESI-MS characterization of the adduct. A reaction mixture of 1 and 3 was irradiated with a 320 nm light source for 15 min in DMSO. Subsequent analysis by ESI-MS evidenced that a new set of peaks is formed, which was assigned to the product of the light-induced Diels-Alder reaction indicating the complete conversion to the photoadduct 6 (Fig 2a). Subsequently, the successful model reaction was adapted to modify the surface of Ag NP.

First, we explored the one pot synthesis in which AgNO₃ is reduced using sodium borohydrate or ascorbic acid in the presence of linker 1 to prepare photoenol decorated Ag NPs. However, the use of such reducing agents leads to the reduction of the aldehyde group to the hydroxyl group in 1, which results in the loss of reactivity (data not shown). To circumvent this drawback, a milder ligand exchange methodology was employed in which the linker is added to the citrate-capped Ag NPs (10 000 eq per NP). To minimize the surface crowding effect, an inert linker 2, which does not contain the photoenol moiety, was used in a 1:10 ratio (linker 1 to linker 2). The combination of reactive and inert linker improved the colloidal stability of the nanoparticles and enable control over the density (and availability) of reactive groups as previously reported. After incubation in DMSO over night at ambient temperature, unbound ligands were removed by centrifugation. The concentration of modified Ag NPs was determined by UV-Vis spectroscopy. The efficient ligand exchange was evidenced via a change in the zeta potential (negative charge of citrate Ag NP decreases ESI, table 2) and X-ray photoelectron spectroscopy (XPS) measurements (Fig. 2b). The C 1s XP spectrum of the modified Ag NPs shows a strong decrease of the peak assigned to O=C-O bonds at 288.5 eV, stemming from the replaced citrate groups. Once the ligand exchange was confirmed, maleimide-PEG 3 was added to the dispersion of modified Ag NPs, purged with nitrogen and irradiated for 15 min at 320 nm (for experimental details please refer to the ESI). After performing washing steps, UV-Vis spectroscopy was employed to evidence that NPs remain stable and no aggregation occurs as indicated by unchanged characteristic plasmonic resonance of Ag NPs at 420 nm (ESI, Fig. S16). XPS analysis of the Ag NPs-modified Ag NPs shows a strong increase of the peak at 286.6 eV in C 1s spectrum, which is assigned to C=O bonds, stemming from the ethylene glycol unit. The formation of a corona of PEG was evidenced by high resolution transmission electron microscopy (HRTEM). As depicted in Fig. 3a, a 1-2 nm PEG shell can be observed around the 20 nm Ag core. To further prove the formation of the corona and its composition energy-dispersive X-ray spectroscopy (EDXS) was carried out. (ESI, Fig. S22). An EDXS line scan along the core shell structure recorded high C content in the shell resulting from the attached PEG layer and high Ag content at the core resulting from Ag NPs. Once the successful light-induced modification of Ag NPs with PEG was demonstrated, the more challenging zwitterionic, non-fouling pCBMA 4 (Mn ~ 21700 g·mol⁻¹) was also grafted to the Ag NPs. A longer irradiation time was used for coupling of pCBMA (1 h vs. 15 min for PEG 3) to compensate for the steric hindrance effects of the longer, highly swollen polymer chain.
The successful photografting was unambiguously confirmed by XPS analysis and EDXS and HRTEM. Namely, the C 1s XP spectrum of Ag NPs 4 shows a strong increase of the peak at 288.5 eV assigned to the O=C-O bonds, stemming from the carboxylic acid and ester groups of pCBMA. In addition, the N 1s XP spectrum shows a new peak assigned to the high energy quaternary ammonium groups (ESI, Fig. S25). HRTEM measurements also demonstrated the formation of the core-shell structure consisting of a 20 nm Ag core and a 4 nm pCBMA shell (Fig. 3b), which was additionally ascertained by an EDXS line scan indicating corresponding Ag and C contents (Fig. 3c+d). It should be noted that control samples – into which both polymers were added without irradiation – did not show any increase in C content via EDX line scans (ESI, Fig.S26 and S27).

In conclusion, we introduce a novel light-induced route for the covalent functionalization of photoenol modified Ag NPs with poly(ethylene glycol) and poly(carboxybetaine methacrylate). The novel bifunctional linker containing benzotriazole as Ag anchoring group and a caged diene (photoenol) moiety enabled photo-grafting to maleimide polymers to Ag NPs as demonstrated by XPS, HRTEM and EDXS. Such light-induced approach to preparation of the polymer Ag NPs expands the synthetic toolbox for the tailoring of nanomaterials and can be translated to the other molecular species. In addition to the potential that Ag NPs could have in biosensing/biomedicine, photoenol modified Ag NPs could be used for light induced patterning onto a range of surfaces – a concept that is the subject of our ongoing studies.
