This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Three-Dimensional NiFe Layered Double Hydroxide Film for High-efficiency Oxygen Evolution Reaction

Zhiyi Lu\textsuperscript{a}, Wenwen Xu\textsuperscript{a}, Wei Zhu\textsuperscript{a}, Qiu Yang\textsuperscript{a}, Xiaodong Lei\textsuperscript{a}, Junfeng Liu\textsuperscript{a}, Yaping Li\textsuperscript{a}, Xiaoming Sun\textsuperscript{*a} and Xue Duan\textsuperscript{a}

Fabricating active materials into specific macrostructures is critical in the pursuit of high electro-catalytic activity. Herein we demonstrate that building a three-dimensional (3D) architecture of NiFe layered double hydroxide (NiFe-LDH) significantly reduced the onset potential, yielded high current density at small overpotentials, and showed an outstanding stability in electrochemical oxygen evolution reaction.

Layered double hydroxides (LDHs), also known as anionic or hydrotalcite-like clays, are composed of layers of divalent and trivalent metal cations coordinated to hydroxide anions, with guest anions (typically CO$_3^{2-}$) intercalated between the layers.\textsuperscript{1, 2} LDHs have been widely studied in fields of catalysts\textsuperscript{3, 4}, flame retardants\textsuperscript{5}, drug delivery hosts\textsuperscript{6}, and as biomaterials\textsuperscript{7}. Recently, their applications as electro-active materials in supercapacitors and fuel cells are attracting considerable attention.\textsuperscript{8, 9} Searching for new compounds composed of abundant and inexpensive elements\textsuperscript{10, 11} as alternatives for traditional OER catalysts, should be the key to developing practical applications of a number of energy storage and conversion processes, including water splitting and metal–air batteries.\textsuperscript{12-15} Latest report demonstrates NiFe-based LDH has shown a superb activity than either of the parent metal catalyst, and comparable to the best noble catalysts (e.g. IrO$_2$ and RuO$_2$) for oxygen evolution reaction (OER).\textsuperscript{16} However, issues of limited specific surface area and conductivity should be further addressed before practical application of LDHs as electrode materials.\textsuperscript{17, 18}

Directly constructing 3D architecture on conductive metal substrates can partially overcome the above issues and thereby bring about a dramatic improvement in the electrochemical performance of the active material.\textsuperscript{19-24} Compared to the conventional 2D planar architecture, electrodes based on 3D porous architecture can offer several critical advantages, such as facilitating electron transportation, promoting electrolyte penetration and increasing the electrochemically active surface area.\textsuperscript{25, 26} Recent work has confirmed the great benefit of 3D architecture on enhancing the OER activity.\textsuperscript{27, 28} Therefore, 3D NiFe-LDH film can be anticipated to show excellent electro-catalytic performance. Moreover, the easy accessibility of LDHs based 3D film\textsuperscript{29} should facilitate their commercial production.

In this work, 3D films of vertically aligned NiFe-LDH nanoplates (NiFe-LDH NPs) loaded on nickel foam have been fabricated for use as electrodes for OER (Fig. 1A). The nickel foam was chosen here (Fig. 1B) because of its zig-zag skeleton and high porosity, which helped to increase the active surface area.\textsuperscript{22, 27} In situ growth of NiFe-LDH NPs resulted in an oriented and rigid 3D architecture, which should help to overcome the problem of low conductivity in conventional LDH films. The electrochemical results demonstrated the NiFe-LDH film could afford a low onset potential (~1.46 V vs. RHE) and a fast current increase, thanks to the synergistic effect of the intrinsically high activity of the catalyst and the unique 3D architecture. Accordingly, only a small overpotential was required (~1.51 V) for achieving 30 mA·cm$^{-2}$ ($\eta_{30}$), better than that of 3D Ni(OH)$_2$ film and 20 wt% Ir/C catalyst. In addition, this catalyst film showed prominent durability when continuously operating OER at high rates.

**Figure 1.** (A), Schematic illustration of NiFe-LDH nanoplates grown on nickel foam; (B), the SEM image of nickel foam; (C) the crystal structure of LDHs.
The 3D NiFe-LDH NP film was synthesized using nickel and iron nitrates as metal source and urea as the precipitant under hydrothermal condition at 120°C (see experimental section). At this temperature, urea decomposed into ammonia which created alkaline environment, and carbonate which served as the intercalated anion. After hydrothermal reaction, a brown film was coated on the surface of nickel foam (Fig. 2A), indicating the successful growth of NiFe-LDH. SEM images of the as-synthesized NiFe-LDH film at different magnifications (Figs. 2B and 2C) showed that the LDH film was mesoporous with nanoplates growing vertically on the Ni substrate. The distance between nanoplates was ~100 nm and the film thickness was approximately 200–300 nm (inset of Fig. 2B). An individual nanoplate from the film had a crumpled and hexagonal morphology, with a lateral size of ~200 nm and was very thin, as revealed by TEM (inset of Fig. 2C). The coincidence of the nanoplate size with film thickness suggested that the NiFe-LDH NPs were directly grown on the Ni substrate as intact units.

Figure 2. (A), optical images of nickel foam before (left) and after (right) growing NiFe-LDH NP film; (B) and (C), low- and high-magnification SEM images of NiFe-LDH NP film, inset: cross-view SEM image and typical TEM image, scale bar: 100 nm; (D), XRD pattern of NiFe-LDH NP film; (E) and (F), XPS spectra of Ni and Fe in NiFe-LDH NP film. These results demonstrate the NiFe-LDH NPs are uniformly and directly grown on nickel foam.

X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) were employed to verify the phase and composition of NiFe-LDH NPs. XRD data showed a series of Bragg reflections, which matched well with the typical profile for LDH materials (the peaks marked “ii” denoted the Ni substrate, Fig. 2D). XPS results confirmed the presence of both Fe and Ni in the film surface (Fig. S1). The binding energy of Ni 2p1/2 and Fe 2p1/2 located on 855.7 eV and 713.7 eV (Fig. 2E and F), respectively, indicating the +2 and +3 oxidation states of Ni and Fe. The atomic ratio of Ni and Fe was ~3:1, confirming the composition of NiFe-LDH along with the XRD data. EDX mapping analysis (Fig. S2) showed that both the nickel and iron elements were homogeneously distributed in the cross-linked 3D architecture.

Such a 3D porous film should promote electrochemical reactions on the electrode surface by exposing more active sites. Therefore we investigated the NiFe-LDH NP films as potential electro-catalytic electrodes for OER in O2 saturated 0.1 M KOH solution using a typical three-electrode setup. The potential calibration of the reference electrode was shown in Fig. S3. A β-Ni(OH)2 NP film (details were shown in Fig. S4) and a pure nickel foam (Fig. S5) were also tested as control samples. Representative cyclic voltammograms (Fig. 3A) revealed that the β-Ni(OH)2 film exhibited two primary characteristics: a redox couple at 1.35 V vs. the reversible hydrogen electrode (RHE), which was attributed to the transformation between Ni(OH)2 and NiOOH; and a positive (oxidation) current at potentials greater than 1.5 V, which was ascribed to OER. These two features were also visible on NiFe-LDH NP film, but there were noticeable differences. The Ni(OH)2/NiOOH redox couple in the LDH film occurred at a higher potential, suggesting the conversion from Ni(II) to Ni(III) was inhibited by the highly charged Fe(III) ions occupying the surrounding positions, consistent with previous reports. However, the OER of LDH started at a less positive potential than that of Ni(OH)2, indicating the NiFe-LDH phase was more desirable for OER. Polarization curve (Fig. 3B) recorded with our NiFe-LDH NP film showed an early onset of ~1.46 V (correlate to overpotential of ~230 mV, which was determined by the start point of Tafel slope), beyond which the anodic current rose rapidly under more positive potentials. Consequently, a high OER rate (e.g. 30 mA·cm−2) could be achieved only requiring a small overpotential (an η10 of ~280 mV), much better than that of β-Ni(OH)2 NP film (~450 mV) and pure nickel foam (~520 mV). It should be noted that the OER activity of NiFe-LDH NP film was even better than 20 wt% Ir/C catalyst (XRD pattern can be seen in Fig. S6), which afforded an onset potential of 1.5 V and a η10 of ~390 mV, highlighting the advanced 3D structural design.

To gain more insight into the OER activity, Tafel plots derived from polarization curves were constructed (Fig. 3C). The resulting Tafel slope of NiFe-LDH NP film was ~50 mV·dec−1, which was smaller than that of β-Ni(OH)2 NP film (~65 mV·dec−1) and Ir/C catalyst (~60 mV·dec−1), indicating the NiFe-LDH NP film exhibited the highest OER activity. The Tafel slope observed for the NiFe-LDH NP film was close to the value (40 mV·dec−1) characteristic of a mechanism involving a pre-equilibrium consisting of a one-electron electrochemical step with a possible chemical step, followed by a one-electron electrochemical rate determining step. Electrochemical impedance results (Fig. 3D) demonstrated that NiFe-LDH possessed a much smaller charge transfer resistance (Rct in the equivalent circuit) than that of β-Ni(OH)2, indicative of a much faster electron transfer process during electrochemical reaction. This may because the broader interlayer spacing of the NiFe-LDH favors the ion diffusion to the active materials.
potentials in 0.1 M and 1 M KOH solution and 20 wt% Ir/C catalyst; porous and nanostructured films. When operating the OER at confirmed by the high stability of Ni(OH)$_2$ for 10 hours (Fig. 4B), further demonstrating the robustness of surface structure of NiFe$_3$LDH NP film was essentially retained after (6.4% and 2.2%, respectively) after 10th testing (Fig. 4A), revealing its excellent stability under OER condition. This was ascribed to the tight binding between the active material and the substrate, which was evidenced by the ultrasonication testing (Fig. S7). Moreover, the surface structure of NiFe$_3$LDH NP film was essentially retained after OER for 10 hours (Fig. 4B), further demonstrating the robustness of the electrode. This benefit afforded by the 3D architecture was confirmed by the high stability of Ni(OH)$_2$ NP film (Fig. S8) while, in contrast, the current density of the drop-cast Ir/C film decreased gradually with time (maintaining less than 80% of the initial current density after 10 h, as shown by the blue line in Fig. 4A). Combining the above merits, this 3D NiFe$_3$LDH NP electrode was among the most active non-precious 3D metal electrocatalysts (see comparison in Table S1).

Figure 4. (A), Stability testing of NiFe$_3$LDH NP film under constant potentials in 0.1 M and 1 M KOH solution and 20 wt% Ir/C catalyst; (B), SEM image of NiFe-LDH after stability testing. These results indicate that NiFe-LDH NP film shows an outstanding stability for OER.

The long-term durability of a catalytic electrode is another crucial issue to consider for practical applications, especially for these porous and nanostructured films. When operating the OER at constant overpotentials, stable corresponding current densities were observed on 3D LDH electrodes, in both 0.1 M (~60 mA·cm$^{-2}$) and 1 M KOH solutions (~200 mA·cm$^{-2}$) with negligible degradations (6.4% and 2.2%, respectively) after 10th testing (Fig. 4A), revealing its excellent stability under OER condition. This was ascribed to the tight binding between the active material and the substrate, which was evidenced by the ultrasonication testing (Fig. S7). Moreover, the surface structure of NiFe$_3$LDH NP film was essentially retained after OER for 10 hours (Fig. 4B), further demonstrating the robustness of the electrode. This benefit afforded by the 3D architecture was confirmed by the high stability of Ni(OH)$_2$ NP film (Fig. S8) while, in contrast, the current density of the drop-cast Ir/C film decreased gradually with time (maintaining less than 80% of the initial current density after 10 h, as shown by the blue line in Fig. 4A). Combining the above merits, this 3D NiFe$_3$LDH NP electrode was among the most active non-precious 3D metal electrocatalysts (see comparison in Table S1).

In summary, a novel 3D porous film consisting of vertically aligned NiFe$_3$LDH NPs was developed to realize high efficient water oxidation. The NiFe$_3$LDH NP film exhibited excellent OER performance with small onset overpotential (~230 mV), low Tafel slope (~50 mV·dec$^{-1}$), large anodic current density (a $\eta_{10}$ of 280 mV) and prominent electrochemical durability. They are mainly attributed to combination of the highly active NiFe$_3$LDH phase with unique hierarchical mesoporous 3D architectures. This study affords a new strategy to achieve optimal performance in 3D catalysts, which may be extended to the preparation of other 3D hybrid materials for a broad range of technological applications.
