Accepted Manuscript

This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
A polymeric nanocapsule encapsulated with 1,1,1,3,3-pentafluorobutane was developed, in which 2,2,3,3,4,4,4-heptrafluoro-1-butyl groups was introduced to the polymer terminal for high loading of liquid fluorocarbon. In vitro experiments demonstrate that its liquid/gas-phase transition can be triggered by mild heating. This nanocapsule can be harnessed as a contrast agent for tumor imaging under diagnostic ultrasound.

As the most widely used cost-effective diagnostic technique, ultrasonography lacks adequate precision and accuracy compared with other major medical imaging modalities. Ultrasonic contrast agents (UCA), represented by gas-filled microbubbles (usually with diameter of 1–7 μm), have served as echo-enhancers to increase the backscattering echo intensity in body fluid. The acoustic impedance, which is proportional to the echo intensity, can be greatly enhanced by the gas in the microbubbles that are usually intravenously administrated. Hereinto, perfluorochemicals (PFC) is the most frequently used content in UCA owing to their strong hydrophobicity, low dispersity, and high biochemical stability.

Although microbubbles have achieved amazing success in clinical practice, their applications in the imaging of capillary-abundant organs or tissues (e.g. tumor) are hindered mainly by their large size. Nano-sized vehicles carrying gaseous or liquid PFCs have shown to be promising approaches to overcome such problems; however, the nanobubbles have rarely been investigated due to their high instability. Nano-droplets of liquid PFCs, such as perfluorohexane (PFH; b.p. 58–60 °C) and perfluorooctyl bromide (b.p. 144 °C), have limitations on compressibility, in vivo persistency, structural stability, and much weaker imaging effects than microbubbles. Phase-change contrast agent (PCCA) based on thermally triggered phase-transition of encapsulated PFC [such as PFH and perfluoropentane (PPF; b.p. 29 °C)], appears to be an attractive option for those applications. Unfortunately, liquid-gas phase transition of PFH can be triggered by hyperthermia under the high intensity focused ultrasound (HIFU), but this operation is risky, invasive, and incapable of simultaneous imaging. PPF-loaded nanoparticles would immediately transform into micron-sized bubble once injected into the body, due to its uncontrollable liquid/gas-phase transition under physiological conditions (~37 °C).

Therefore, 1,1,1,3,3-pentafluorobutane (PFB; b.p.: 40 °C), which is structurally similar to PFC, is introduced as the inner droplet of nano-sized PCCA. Based on the higher temperature gradients of tumor region than surrounding normal tissue, PFB may readily undergo liquid/gas-phase transition with the aid of mild hyperthermia caused by low-intensity ultrasound (including clinical diagnostic ultrasound). PFB-loaded nanoparticles can be triggered to balloon till entering into tumor. Undoubtedly, this controllable transition of PFB under diagnostic ultrasound would avoid the uncontrollable liquid/gas-phase transition of PPF as well as the application of HIFU, thus could offer a safer and more convenient mode of imaging. Amphiphilic biodegradable block copolymer such as methoxy-poly(ethylene oxide)-b-poly(ε-caprolactone) (mPEG-PCL) has been used as the less gas-permeable “surfactant” to stabilize inner fluorocarbon droplet or bubble, to increase bubble resistance to pressure and to prolong blood circulation time. Furthermore, according to previous reports, mPEG-PCL encapsulated with 2,2,3,3,4,4,4-heptafluoro-1-butyl group (HFB) may have better compatibility with PFB and facilitate the formation of nano-sized polymeric PCCA.

In this paper, PFB nano-droplets were stabilized by HFB-replaced mPEG-PCL through an ultrasonic triple-emulsification process. In detail, liquid fluorocarbon (PFB or PHF) was first dispersed as droplets in dichloromethane (DCM), and then covered with copolymer chains to form aqueous emulsion under twice ultrasound action. After the removal of residual DCM, fluorocarbon-loaded polymeric nanocapsules with liquid core would be constructed in the stable form. This structure of these nanocapsules was confirmed by the transmission electron microscope (TEM) image of PFH-loaded mPEG-PCL-HFB nanocapsules (Figure 1). Uniform hollow spheres with diameter of about 600 nm could be observed with irregular loophole, which could be conceivably originated from the exhaustion of gasified PFH under high vacuum. Such observation clearly indicated that polymeric nanocapsule with the core of PFH was successfully constructed, and then cavitated by the gasification of PFH till burst. However, in the case of PFB, no such expansion or burst were observed under TEM; this could probably be attributed to the much higher volatility of PFB, which allows the droplet to evaporate too rapidly to generate the inner cavitation of the nanocapsules. Hereinto, mPEG-PCL and mPEG-PCL-HFB block copolymers with defined structure (molecular weight (M.W.) of PEG
block: 2,000 g/mol; M.W. of PCL block: 10,000 g/mol] were used. The particle sizing revealed that both copolymers could form nanosized particles with the mean diameter ranging from 130 nm to 150 nm (Table 1). This size range would ensure the entry of these nanocapsules into tumor tissues through the gaps of vascular endothelium. According to the Ideal Gas Law, this size range would also ensure that most polymeric nanocapsules could expand to micron-scale upon the gasification of the encapsulated liquid fluorocarbon.

Figure 2. Compatibility tests of copolymers and PFB: the static water contact angle (A), the calorimetric curves of blank (B), and PFB-loaded nanocapsules (C).

Not surprisingly, the DSC curve of blank mPEG-PCL was quite similar to those in literatures, and that of blank mPEG-PCL-HFB displayed somewhat difference in cold crystallization temperatures (T_{cc}) and crystallinity. After encapsulation of fluorocarbon, the T_{cc} of lyophilized mPEG-PCL and mPEG-PCL-HFB nanocapsules increased from about 40 °C to above 45 °C. Naturally, the hydrophobic interaction between PCL blocks and liquid fluorocarbon would help PCL blocks to form a well-organized hydrophobic layer on the surface of liquid fluorocarbon, which contributes to the enhanced crystallization of semicrystalline PCL blocks with higher T_{cc}. The presence of the HFB group would further reinforce this interaction and induce higher crystallinity of PCL blocks (Table 2); as a result, the mPEG-PCL-HFB
acoustic impedance and bubbles were visible when the temperature was 201. Particularly, PFB...manuscript, 1 ample, the encapsulation efficiencies of PFH and PFB were...

Table 2. Thermal properties of blank and PFB-loaded nanocapsules.

The liquid-gas phase transition of fluorocarbon-loaded polymeric nanocapsules was visualized at determined temperature on a programmed heating stage under microscope (Figure 3). More visible micron-sized spherical bubbles appeared as the sample being heated from room temperature to the b.p. of fluorocarbon or higher temperature. Initially, very few microbubbles could be observed at 37 °C; more microbubbles were visible when the temperature was raised to slightly higher than boiling point of corresponding fluorocarbon, indicating the liquid-gas phase transition of fluorocarbon occurred inside the nanocapsule at elevated temperature. Quantification of microbubbles at determined temperature clearly indicated that the introduction of HFB group had significantly increased the number of microbubbles at elevated temperature. This could be explained by the higher encapsulation efficiency of liquid fluorocarbon as evidenced by chromatographical measurement (Table 1, and Figure S3 in ESI). Particularly, PFB-loaded nanocapsules generated much more microbubbles after grafting HFB groups to the mPEG-PCL copolymer as compared with their counterparts; at 41 °C, the number of microbubbles significantly increased from 9 to 38. Those findings proved that these nanocapsules with liquid nanodroplets of PFB or PFH inside have the potential to generate micron-sized bubbles under mild heating. Since tumor tissue has higher acoustic impedance and slightly higher temperature compared with normal tissue, a temperature slightly higher than 40 °C can be readily achieved based on the mild hyperthermia effect under low intensity ultrasound. Thus the above PFB-loaded nanocapsules could be harnessed for in vivo imaging of tumor tissue under low intensity ultrasound such as diagnostic ultrasound.

Figure 3. Visualization of the liquid-gas phase transition of polymeric nanocapsules loaded with PFH (A) and PFB (B) at different temperature under microscope. (Scale bar: 5μm)

*In vitro* ultrasound imaging test of these nanocapsules was performed utilizing an agarose model. PFB-loaded nanocapsules exhibited remarkably enhanced imaging at 40 °C where more off-white dots emerged compared with the initial stage (Figure 4A). After background subtraction, two times-diluted PFB-loaded mPEG-PCL-HFB nanocapsule (labelled mPEG-PCL-HFB-2X) exhibited enhanced gray values for about 30 second (s), and mean gray values were higher than background by at least 10 for about 17 s (Figure 4B). It proved that PFB-loaded mPEG-PCL-HFB nanocapsules could produce strong and long-lasting contrast. Since the UCA would be diluted in the circulation system after IV administration, difference dilutions of the nanocapsule solution were also test (Figure 4C) under same conditions. Clearly, 40 times-diluted nanocapsule solution still exhibited weakly enhanced imaging as compared with background, indicating the feasibility of intravascular and blood-pool imaging by intravenous injection (Figure 4D).
Conclusions

Liquid fluorocarbon-encapsulated polymeric nanocapsules were constructed, in which the HFB groups in the block copolymer could greatly enhance the loading capacity of liquid fluorocarbon. In vitro ultrasound imaging demonstrated that the liquid/gas phase transition and resulting imaging of nanocapsules could be triggered by mild hyperthermia. This novel approach has paved the way for accurate imaging within tumor region via mild hyperthermia of diagnostic ultrasound. More efforts on the improvement in expansion ratio, optimization of nanocapsule concentration, and even introduction of targeting ligands for tumor-specific ultrasound molecular imaging would be the focus of the future study.

The authors thank Mr. Yihan Jing for his assistance in microscopic observation.
