This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Improved Electrocatalytic Activity for Ethanol Oxidation by Pd@N-doped Carbon from Biomass

Haiyan Jin, Tianyi Xiong, Yi Li, Xuan Xu, Mingming Li and Yong Wang *

Pd@N-doped carbon (Pd@CN) exhibited four and two times higher peak current density toward ethanol electrooxidation than Pd@active carbon and Pd@non-nitrogen carbon. Controlled experimental results indicated that the incorporation of nitrogen into the carbon matrix improved the percentage of Pd\textsuperscript{0} and increased the binding energy of Pd in Pd@CN, and accordingly enhancing the catalytic activity.

Accelerated depletion of fossil fuels, coupled with concerns over environmental pollution, poses great demands for renewable and clean energy sources.\textsuperscript{1} From this standpoint of view, ethanol possesses distinct advantages over methanol, gas fuels etc. owing to its high energy density, low toxicity, easy storage and transportation, and large scale of production from biomass.\textsuperscript{2} Accordingly, direct ethanol fuel cells (DEFCs) have been extensively studied in efforts as power sources for portable electronic devices and fuel cell vehicles. However, it is quite difficult to completely oxidize ethanol which involves breaking C-C bond and releasing 12 electrons.\textsuperscript{3} Moreover, many adsorbed intermediates (mainly CO and -CHO) produced during the oxidation reaction poison the anode catalysts and in turn reduce the catalytic efficiency.\textsuperscript{4} Therefore, it necessitates high activity and stability electrocatalysts to accelerate this reaction.

It’s well known that Pd is a promising electrocatalyst for ethanol oxidation in basic media.\textsuperscript{5} Great research efforts have been devoted to adding a second element such as Sn\textsuperscript{6}, Ni\textsuperscript{7}, Bi\textsuperscript{8}, Ag\textsuperscript{9}, Au\textsuperscript{10}, Pb\textsuperscript{11} to Pd supported on carbon materials to optimize the electrocatalytic performance and stability of Pd toward ethanol oxidation in alkaline media because of the bimetallic synergistic effect. However, the influence of support materials on the valence state, size distribution, stability and dispersion of Pd which further affects its catalytic property and efficiency cannot be overlooked.\textsuperscript{12}

Currently, nitrogen-doped carbon materials as supports have received particular attention to researchers due to their remarkable performance in various applications, such as hydrocarbon oxidation\textsuperscript{13}, hydrogenation of unsaturated bond\textsuperscript{14}, biomass refining\textsuperscript{15}, etc. Furthermore, the use of inexpensive, sustainable feedstocks to produce N-doped carbon materials conforms to the concept of green chemistry.\textsuperscript{16} And the reasons may contribute to the fact that the incorporation of electron-rich nitrogen atoms modifies the surface structure of carbon materials, demonstrating improved π-binding ability, more defects and strengthened interaction between metal nanoparticles (NPs) and supports.\textsuperscript{17}

Based on the above considerations, herein, N-doped mesoporous carbon material from D-glucosamine hydrochloride, a harmless and naturally available biomass, was utilized as a basic support to construct Pd catalysts (Pd@CN, the content of nitrogen in CN is about 7.0%) towards ethanol oxidation in alkaline media. Compared to Pd@HC (non-nitrogen hydrothermal carbon from glucose) and the commercially available Pd@AC, Pd@CN demonstrated superior catalytic performance for ethanol oxidation. The influences of pore structure and surface area of supports and valence state and morphology of metal palladium were investigated in detail towards ethanol oxidation. Physical and electrochemical data indicated that the incorporation of nitrogen could enhance the percentage of Pd\textsuperscript{0} and increase the binding energy of Pd in Pd@CN which produced superior catalytic activity.

To evaluate the catalytic properties of Pd@CN versus Pd@HC and Pd@AC catalysts toward ethanol oxidation, we performed the electrooxidation reaction of these catalysts in 1 M C\textsubscript{2}H\textsubscript{5}OH + 1 M KOH. The CVs at 50 mV/s (Fig. 1a) show that the specific peak current density of Pd@CN is almost two and four times higher than that of Pd@HC and Pd@AC when the current density is normalized to per unit mass of Pd. In addition, the onset potential of the forward scan direction of Pd@CN is remarkably lower than that of Pd@HC and Pd@AC, which is an evidence that Pd@CN overtakes Pd@HC and Pd@AC in the kinetics of ethanol oxidation reaction.\textsuperscript{18}

Fig. 1. (a) CVs of Pd@AC, Pd@HC, and Pd@CN in 1 M C\textsubscript{2}H\textsubscript{5}OH + 1 M KOH solution at 50 mV/s. (b) Chronoamperometric curves of three catalysts measured in the solution of 1 M KOH + 1 M C\textsubscript{2}H\textsubscript{5}OH at -0.35V.
To further confirm the high catalytic activity of Pd@CN, cyclic voltammetry tests of three catalysts were carried out in 1 M CH₃OH + 1 M KOH solution at a scan rate of 50 mV/s (Fig. S1, ESI†). It is evident that Pd@CN still shows higher activity towards methanol oxidation than Pd@HC and Pd@AC. The electrochemical stability of these catalysts for ethanol oxidation was then investigated by chronoamperometric experiments at a given potential of −0.35 V in 1.0 M KOH + 1.0 M C₂H₅OH solution (Fig. 1b). As shown that Pd@CN exhibits a slower current decay over time in comparison with Pd@HC and Pd@AC, proving a higher tolerance to carbonaceous species generated during ethanol oxidation.¹⁹

The above results demonstrate Pd@CN exhibits higher electrocatalytic activity and better durability than Pd@HC and Pd@AC. It has been proven that the dispersion and valence state of Pd and structure properties (BET surface area, pore structure) of supports can affect the activity of catalysts.²⁰ The following detailed discussions elaborated the decisive factors in perfecting the performance of Pd@CN towards ethanol oxidation.

As presented in Fig. 2, the Pd NPs are uniformly dispersed on supports. Size distribution histograms demonstrate the average particle sizes of Pd@AC, Pd@HC, and Pd@CN are 3.79, 3.52, and 3.40nm, respectively, suggesting similar size distributions. Moreover, the dispersions (D) of Pd in Pd@AC, Pd@HC, and Pd@CN, i.e., the fraction of exposed Pd in the catalyst are determined to be 0.26, 0.28, and 0.29, respectively (ESI†).²¹ The similar particle size and dispersion of Pd in catalysts make it possible to eliminate the effect of metal particle size and dispersion on ethanol electrooxidation activity.²² The XRD patterns of three catalysts (Fig. S2, ESI†) together with the TEM images indicate similar metal morphology structure²³, excluding the influence of metal crystal structure on ethanol oxidation in this case, which inspires us to further discuss other factors influencing catalyst performance.

The pore structure and surface area of AC, HC, and CN were then investigated by N₂ adsorption-desorption isotherms. As shown in Fig. 3a and b, AC mainly consists of micropores and mesopores, and accumulated pores dominate HC with wide pore distribution. Meanwhile, CN exhibits a IV-type isotherm with a distinct hysteresis loop, indicating the mesoporous nature. Though the BET surface area of CN (324 m²/g) and HC (115 m²/g) are smaller than AC (899 m²/g) (Table S1, ESI†), their electrocatalytic performances as supports are still superior to AC, indicating the larger surface area doesn’t always produce better catalytic activity. The larger pore size distribution of CN (8nm) and HC (34nm) could yield easier mass transportation and consequently better performance towards ethanol oxidation than AC with pore diameter of 4nm (Table S1, ESI†).²⁴ Though the pore volume of CN is smaller than HC, it still presents better activity. The above results illustrate that proper BET surface area, pore size and pore volume are necessary to improve ethanol electrooxidation activity of catalysts. The Pd₃₄₃ X-ray photoelectron spectroscopies (XPS) of three catalysts are shown in Fig. 4. The survey XPS spectrum of Pd@CN confirms the incorporation of nitrogen into carbon materials (Fig. S3, ESI†). The Pd₃₄₃ signal of Pd@HC catalyst is fitted to two pairs of doubles: Pd₃₄₃ (337.4 eV), Pd₃₄₃ (335.9 eV) and Pd₃₄₃ (342.3 eV), Pd₃₄₃ (341 eV), which can be ascribed to Pd³⁺ and Pd²⁺ species, respectively.²⁵ However, the binding energy of Pd³⁺ (341.7 eV, 336.5 eV) and Pd²⁺ (338.2 eV, 343.6 eV) in Pd@CN positively shift compared with that of CN (Fig. S4 and Table S3, ESI†), implying a transfer of electron density from N to Pd.²⁶ Therefore, the incorporation of nitrogen is beneficial to the reduction of Pd⁴⁺ to Pd³⁺ due to the electron donation effects of nitrogen, which provides more active sites and accordingly will improve the catalytic activity of Pd@CN.²⁷ This can also be confirmed by the fact that Pd@CN possesses the most percentage of Pd³⁺ (70.0%) among three catalysts due to the N-doping effect (Table S2, ESI†). Moreover, the positive shift of binding energy of Pd can be attributed to the introduction of nitrogen, which reflects the downshift of d-band center of Pd atom in Pd@CN and consequently results in the decrease in the interaction strength of various adsorbents to Pd surface.²⁷,²⁸

To further illustrate the nitrogen-doping effect on ethanol electrooxidation, we performed CVs and CO stripping experiments.
on three catalysts in 1.0 M KOH solution at 50 mV/s (Fig. 5). The calculated electrochemically surface area (ECSA) of Pd@CN catalyst is 1.9 and 1.4 times greater than Pd@AC and Pd@HC (Table S1, ESI†). The above results prove that a higher proportion of Pd is electrochemically available in Pd@CN than Pd@HC and Pd@AC. As shown in Fig. 4d, the ECSA presents some degree of linear relationship with the percentage of Pd, again revealing the effect of N-doping on the improved percentage of Pd in CN. We also compared the surface area normalized activity (A/m²) based the electrochemical surface area of Pd in Fig. S5 (ESI†). Results also show that Pd@CN catalyst still offers much higher electrocatalytic activity than Pd@HC and Pd@AC. The results of CO stripping experiments on three catalysts are shown in Fig. 5b, c and d. An obviously larger CO oxidation peak than that on Pd@HC and Pd@AC catalyst in the initial forward scan is observed on Pd@CN catalyst owning to a larger ECSA of Pd. In addition, the initial potential of CO oxidation on Pd@CN (-0.35 V) is slightly more negative than that of on Pd@HC (-0.34 V), but significantly lower than Pd@AC (-0.25 V) in first forward scan. These results can be attributed to the introduction of N which lower the adsorption strength of CO and facilitate removal of CO on the surface of catalyst. The disappearance of CO oxidation peaks after stripping and reappearance of hydrogen peaks at negative potentials indicate that both catalysts are free of dissolved CO.

Conclusions

In conclusion, we applied a biomass-derived nitrogen-doped carbon material as a desired support of Pd to direct ethanol fuel cells. Compared to Pd@AC and Pd@HC, Pd@CN exhibited four and two times higher peak current density toward ethanol oxidation, respectively. Research results illustrated that proper BET surface area, pore size, and pore volume were beneficial to improving the ethanol electrooxidation activity of catalysts. XPS experiments further proved that the introduction of nitrogen into carbon matrix improved the percentage of Pd and increased the binding energy of Pd in Pd@CN, and accordingly enhancing the catalytic activity, durability and CO tolerance of catalyst. Thus, nitrogen-doped carbon materials as high-performance catalyst supports have great promising application in direct ethanol fuel cells.
