This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Li$_3$VO$_4$ were anchored to graphene nanosheets (Li$_3$VO$_4$@GNS) using a sol-gel method. The composite presents excellent high-rate performance with a stable capacity of 133 mAh/g at 50C and long-life performance with capacity retention rate of 63.1% after 5000 cycles at 5C.

Lithium-ion batteries (LIBs) have been widely used as power sources for portable electronics with potential applications in electric vehicles and large-scale energy storage devices because of their high energy density, high power density, and environmentally friendly features. Graphite is commonly used as anode materials in most commercial LIBs. However, graphite reaches almost 0 V vs. Li$^+$/Li at the end of the discharge process, which potential dendritic lithium could grow on the anode surface and leads to safety issues. Spinel Li$_4$Ti$_3$O$_12$ has attracted wide attention as a promising anode material because of its minimal volume change and relatively high voltage during Li$^+$ insertion/extraction. Although Li$_4$Ti$_3$O$_12$ shows good cyclability and high safety, it suffers from low capacity (175 mAh/g) and relatively high intercalation potential at 1.54 V vs. Li$^+$/Li. Recently, Li$_3$VO$_4$ has attracted increasing attention as a new anode material with suitable intercalation potential between 0.5 and 1 V vs. Li$^+$/Li. The potential is lower than that of Li$_4$Ti$_3$O$_12$ and higher than that of graphite. The theoretical capacity of Li$_3$VO$_4$ is 394 mAh/g, corresponding to a two-Li intercalation into the Li$_3$VO$_4$ structure. Furthermore, Li$_3$VO$_4$ has high ionic conductivity and has been studied as an ionic conductor for many years. In contrast, the electronic conductivity of Li$_3$VO$_4$ is quite low and results in large resistance polarization and poor rate performance. To improve the electrochemical performance, improving the electronic conductivity and reducing particle size by growing inorganic nanoparticles on graphene has been proved to be an effective approach.

In this study, we synthesized Li$_3$VO$_4$@GNS nanocomposite as a novel anode material for LIBs, where Li$_3$VO$_4$ nanoparticles were embedded in graphene nanosheets (GNS). This nanocomposite was obtained using a sol-gel method. Li$_3$VO$_4$ formed as fine crystals uniformly on GNS. Li$_3$VO$_4$@GNS delivers excellent rate performance and cycling stability. Pristine Li$_3$VO$_4$ simply mixed with GNS was also prepared for comparison. Electrochemical impedance spectroscopy (EIS) was used for better understanding of the function of the composite.

Graphite oxide (GO) was synthesized from natural graphite powders using a modified Hummers method. After thermal exfoliation of GO, GNS with porous structure was obtained, which provide space to accommodate other materials. Furthermore, the large amount of functional groups on the surface of GNS can supply adsorption sites for different ions. Therefore, Li$_3$VO$_4$@GNS composite can be prepared using the sol-gel method with the schematic illustration shown in Figure 1. First, V$_2$O$_5$ powders were added into LiOH solution in stoichiometric quantity of forming Li$_3$VO$_4$. After dissolving V$_2$O$_5$, a yellow solution was obtained with the formation of VO$_3^-$ ions, after which GNS was added and stirred overnight to obtain black sediment. After calcination at 600 °C for 2 h, Li$_3$VO$_4$@GNS was obtained as the final product (equation (2)).

$$2\text{OH}^- + \text{V}_2\text{O}_5 \rightarrow 2\text{VO}_3^- + \text{H}_2\text{O} \quad (1)$$

$$\text{Li}_3\text{VO}_4 + 2\text{LiOH} \rightarrow \text{Li}_3\text{VO}_4 + \text{H}_2\text{O} \quad (2)$$

More details of experimental procedure are given in the supplementary information.
Li$_3$VO$_4$@GNS sample, a bump exists at around 25°, which could be assigned to that of the GNS. Raman spectroscopy is a powerful tool for characterizing graphitic structures. The peaks between 200 ~ 500 cm$^{-1}$ and 750 ~ 1000 cm$^{-1}$ are attributed to the Raman peaks of Li$_3$VO$_4$, which are in good agreement with the findings of previous work.$^{34}$ However, the intensity of these peaks for Li$_3$VO$_4$@GNS decreases sharply, indicating that Li$_3$VO$_4$ is well embedded inside the GNS and thus hardly detectable by Raman spectroscopy. Two additional peaks located at 1345 cm$^{-1}$ and 1595 cm$^{-1}$ for Li$_3$VO$_4$@GNS sample are attributed to the characteristic Raman peaks of the D-band and G-band of the graphitic material, respectively. The 26 wt.% content of GNS in the Li$_3$VO$_4$@GNS composite was estimated from thermogravimetric analysis (Figure S2).

**Figure 2** (a) XRD patterns and (b) Raman spectra of the pristine Li$_3$VO$_4$ and Li$_3$VO$_4$@GNS composite.

Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) were used to further study the morphology of two samples. Figure 3a shows pristine Li$_3$VO$_4$ particles with two different sizes: bigger particles around 0.5-1 nm and smaller ones around 20-50 nm. Considering the XRD results in Figure 2a, the sol-gel synthesis of Li$_3$VO$_4$ produces nanoparticles around 20-50 nm. During the calcination step, some of these nanoparticles aggregate to form large particles. Figure 3b shows the interplanar spacing of the crystals of 0.37 nm, corresponding to the (101) plane. In the presence of GNS, the aggregation of Li$_3$VO$_4$ nanoparticles becomes more restricted with mostly small nanoparticles in 10-30 nm and less percentage of larger particles around 500 nm (Figure S5). Li$_3$VO$_4$@GNS sample also shows a high degree of crystallinity. The displayed crystalline interplanar spacing of 0.39 nm in Figure 3d corresponds to the (011) planes. The presence of Li$_3$VO$_4$/GNS composite was further confirmed by the selected area electron diffraction (SAED) pattern (inset of Figure 3d) owing to its characteristic diffraction rings and spots. The diffraction spots correspond to (002) and (004) planes of GNS. The diffraction spots are indexed as crystals of Li$_3$VO$_4$, which are in good agreement with the XRD results.

The electrochemical performance of the Li$_3$VO$_4$@GNS composite was analyzed in CR2032 coin cells. Figure 4a shows the first three cycles of discharge/charge curves at a rate of 0.5C (note that 0.5C refers to two Li insertion into Li$_3$VO$_4$ per formula unit in 2 h). The initial discharge/charge capacity is 45744/486 mAh/g, resulting in an irreversible capacity loss of 42%, which might be due to the formation of the solid electrolyte interface (SEI) film. The subsequent coulombic efficiency is improved over cycles; the coulombic efficiency for the second cycle can reach 94.6%. Cyclic voltammetry measurement was also performed and the corresponding first three cycles of the CV curves at a scan rate of 0.05 mV/s are shown in Figure 4b. For the first cycle curve, two reduction peaks are found at 0.62 and 0.52 V, which shift to 0.86 and 0.53 V in the subsequent cycles, indicating a phase transformation during Li insertion. Only one broad oxidation bump around 1.34 V can be observed in the first three cycles, indicating similar lithium extraction mechanism.

We also investigated the rate performance of the Li$_3$VO$_4$@GNS composite. Stable capacity are observed at about 400, 350, 310, 256, 215, 175, and 133 mAh/g at rates of 0.5C, 1C, 2C, 5C, 10C, 20C and 50C, respectively (Figure 4c), with ~90% of which coming from Li$_3$VO$_4$ instead of GNS at all rates (Figure S6). Compared with the pristine Li$_3$VO$_4$ sample, simply mixed with 26 wt.% of GNS as conductive additive, Li$_3$VO$_4$@GNS composite shows higher capacity, especially at high rates. For instance, Li$_3$VO$_4$@GNS composite delivers a capacity of about 133 mAh/g at 50C (8 mAh/g contributed from GNS), whereas the capacity of pristine Li$_3$VO$_4$ is almost zero. The significantly improved rate performance of this composite is attributed to the presence of small Li$_3$VO$_4$ particles and close contact between Li$_3$VO$_4$ particles and GNS, which reduce Li$^+$ ion diffusion distance and increase the electronic conductivity. Figure 4d shows the EIS results of pristine Li$_3$VO$_4$ and Li$_3$VO$_4$@GNS before and after discharge/charge. The Nyquist plots show a semicircle and a quasi-straight line (which represents the Warburg impedance, $Z_w$), which are associated with the charge transfer resistance ($R_{ct}$) and impedance of Li$^+$ diffusion in solid materials, respectively. Moreover, the values of $R_{ct}$ for Li$_3$VO$_4$@GNS are obviously lower than those of pristine Li$_3$VO$_4$, indicating better electronic contact of the Li$_3$VO$_4$@GNS electrode. The values of $R_{ct}$ decrease after discharging/charging both electrodes, indicating a
decrease in resistance after cycling. The long-life performance of Li$_3$VO$_4$@GNS is shown in Figure 4e. The capacity can be maintained at 163 mAh/g at a rate of 5C after 5000 cycles, which is close to the theoretical capacity of Li$_3$Ti$_2$O$_12$. A capacity retention of about 63.1% and a coulombic efficiency close to 100% has been obtained after activation at 0.5C for five cycles. The excellent long-life performance can be ascribed to the unique structure, in which Li$_3$VO$_4$ nanoparticles are well embedded inside GNS to form a structurally stable composite material (Figure 7S).

**Figure 4** (a) Galvanostatic discharge and charge profiles of the Li$_3$VO$_4$@GNS composite in the voltage range of 0.2 – 3 V vs Li/Li$^+$ at a rate of 0.5C; (b) Corresponding cyclic voltammetry of the Li$_3$VO$_4$@GNS at a scan rate of 0.05 mV/s; (c) Discharge and charge capacities of the pristine Li$_3$VO$_4$ and Li$_3$VO$_4$@GNS composite at different C-rates; (d) Nyquist plots for the pristine Li$_3$VO$_4$ and Li$_3$VO$_4$@GNS composite before (solid) and after (hollow) first cycling; (e) long-life performance of Li$_3$VO$_4$@GNS composite at 5C. All capacity calculation is based on the mass of Li$_3$VO$_4$.

In summary, we have designed a facile method to fabricate Li$_3$VO$_4$@GNS composite, in which Li$_3$VO$_4$ nanoparticles (about 10–30 nm) are well embedded in GNS. This novel Li$_3$VO$_4$@GNS composite has been investigated as an anode material for LIBs. The composite presents excellent high-rate performance with a stable capacity of 133 mAh/g even at 50C. After 5000 cycles at a rate of 5C, its capacity maintained at 163 mAh/g, which is 63.1% retention of the original reversible capacity. This result can be attributed to the formation of a conducting network of mixed Li$^+$ ions and electrons, as well as the protection provided by GNS in terms of reducing the side reaction between Li$_3$VO$_4$ and electrolyte. These excellent properties make Li$_3$VO$_4$@GNS composite a promising anode candidate for LIBs.
