This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Electrochemistry and Structure of the Cobalt-free Li$_{1+x}$MO$_2$ ($M = $ Li, Ni, Mn, Fe) Composite Cathode

Wei Kong Pang,$^{ab}$ Sujith Kalluri,$^b$ Vanessa K. Peterson,$^{*,a}$ Shi Xue Dou,$^b$ and Zaiping Guo$^{*,b}$

The development of cathode materials with high capacity and cycle stability is essential to emerging electric-vehicle technologies, however, of serious environmental concern is that materials with these properties developed so far contain the toxic and expensive Co. We report here the Li-rich, Co-free Li$_{1+x}$MO$_2$ ($M = $ Li, Ni, Mn, Fe) composite cathode material, prepared via a template-free, one-step wet-chemical method followed by conventional annealing in an oxygen atmosphere. The cathode has an unprecedented level of cation mixing, where the electrochemically-active component contains four elements at the transition-metal (3$d$) site and 20% Ni at the active Li site (3$p$). We find Ni$^{2+}$/Ni$^{3+}$/Ni$^{4+}$ to be the active redox-center of the cathode with lithiation/delithiation occurring via a solid-solution reaction where the lattice responds approximately linearly with cycling, differing to that observed for iso-structural commercial cathodes with a lower level of cation mixing. The composite cathode has ~ 75% active material and delivers an initial discharge-capacity of ~ 103 mAh.g$^{-1}$ with a reasonable capacity retention of ~ 84.4% after 100 cycles. Notably, the electrochemically-active component possesses a capacity of ~ 139 mAh.g$^{-1}$, approaching that of the commercialized LiCoO$_2$ and Li(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$ materials. Importantly, our operando neutron powder-diffraction results suggest excellent structural stability of this active component, which exhibits ~ 80% less change in its stacking-axis than for LiCoO$_2$ with approximately the same capacity, a characteristic that may be exploited to enhance significantly the capacity retention of this and similar materials.

Introduction

Since the introduction of the first commercial Li-ion battery containing LiCoO$_2$ as the cathode and graphite as the anode by Sony in 1991, the Li-ion battery has become the preferred choice for powering portable electronic-devices. Despite a theoretical capacity of 274 mAh.g$^{-1}$, the practical capacity of LiCoO$_2$ is restricted to 140 mAh.g$^{-1}$ as a consequence of structural stability issues, where only half of the Li can be removed before the structure decomposes into CoO$_2$. Moreover, LiCoO$_2$ has a relatively-poor rate capability and contains toxic and expensive Co. The world Co price is currently determined by Li-ion battery demands, and the present and significant research effort to find alternative, Co-free cathodes that are environmentally-friendly with good electrochemical performance is of great global importance. Ni and Mn have been used to replace Co to form the alternative cathode materials LiNiO$_2$ and LiMnO$_2$, respectively. Although Co-free, these materials are difficult to prepare and thermally unstable at their charged state. Importantly, to date Co-free cathodes have suffered significantly from poor structural stability. For example, the Li$_2$MnO$_3$ cathode and its derivatives exhibit severe capacity-decay, despite an initial discharge-capacity exceeding 200 mAh.g$^{-1}$ after charging beyond 4.6 V with Jahn-Teller distortion of Mn$^{3+}$ contributing significantly to instability on cycling. The cycling performance and stability of a battery is of utmost importance and in commercial use capacity is sacrificed to achieve this. Cycle stability and good battery-lifetime are achieved industrially through constraints on the cycle depth, ensuring structural stability at the expense of capacity, where constraint of the discharge to 40% is commonplace. Whilst stabilizing the bulk of the cathode, this approach does not prevent cathode destabilization as a result of local clusters of fully-transformed material, with the macroscopic lithiation mechanism a significant influence on this. One method to overcome this is to incorporate redox-inert transition-metal centers into the material, which stabilize the structure during charge-discharge cycling. The mixed transition-metal Li(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$, iso-structural to LiCoO$_2$ and reported by Yabuuchi and Ohzuku, is now commercially-used. Although Mn and Co are electrochemically inert in the active voltage range of Li(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$, the valence of Ni changes from 2+ to 4+ and effectively doubles the capacity, with the reversible capacity of this cathode in excess of 200 mAh.g$^{-1}$. The inert redox centers in Li(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$ make this
material more stable than LiCoO$_2$,\textsuperscript{18} although the presence of Co and the relatively-poor rate performance of Li(Ni$_1$Mn$_{1/3}$Co$_{1/3}$O$_2$)O$_2$ remain problems. Although mixed transition-metal oxides with a further reduced amount of Co have been synthesized, such as LiMn$_{0.5}$Ni$_{0.2}$Co$_{0.3}$O$_2$ and LiMn$_{0.42}$Ni$_{0.45}$Co$_{0.13}$O$_2$,\textsuperscript{19-21} expensive and toxic Co remains. More recently, the novel, eco-friendly, and Co-free Li(Ni$_{1/3}$Mn$_{1/3}$Fe$_{1/3}$)O$_2$ was reported, with a theoretical capacity of 281 mAh$\cdot$g$^{-1}$, exceptional rate-performance, and the reasonably-high practical discharge-capacity of 170 mAh$\cdot$g$^{-1}$ in the presence of a conducting polyaniline network. The evolution of metal-oxide cathodes from the first LiCoO$_2$ material to Li(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$ and Li(Ni$_{1/3}$Mn$_{1/3}$Fe$_{1/3}$)O$_2$ materials, stands testament to the importance of the serious environmental concerns in the interest of the application of cathodes for low or zero-emission transportation such as to power hybrid-electric and electric vehicles, where both high capacity, cycle stability, and good rate-performance are required.

An alternative to mixed transition-metal oxides as highly stable cathode materials is the use of an additional and inactive phase, such as the superlattice-structured Li$_3$MnO$_2$\textsuperscript{22-24}. Here the cathode functions as a composite, where the Li$_2$MnO$_3$ offers additional stability during high-voltage charge.\textsuperscript{22-25} Following this theory, new cathodes with excess Li are being created, such as the Li$_3$Mn$_{0.5}$Ni$_{0.3}$Mn$_{0.2}$O$_2$ composite, with the aim of improving both cycling stability and capacity for future Li-ion battery applications.\textsuperscript{26-28}

In order to direct the development of cathodes with improved performance, the atomic-level structural response of LiCoO$_2$\textsuperscript{4} and Li(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$\textsuperscript{29} during lithiation and delithiation have been studied. Delithiation in LiCoO$_2$ is reported to proceed through a solid-solution reaction to form Li$_x$CoO$_2$ ($x = \sim 0.5$ with capacity $\sim 140$ mAh$\cdot$g$^{-1}$), with further Li extraction inducing the formation of CoO$_2$ via a two-phase reaction.\textsuperscript{3,4} During the solid-solution reaction, the lattice parameter $c$ first increases, before decreasing at the charged state. This reversible non-linear behaviour is also observed in the iso-structural Li(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$ cathode.\textsuperscript{18, 29} Under further delithiation, Li(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$ decomposes via a two-phase reaction, forming the Li$_{0.04}$(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$ material with space group $P\bar{3}m1$.\textsuperscript{18} The generally-accepted explanation for the non-linear behaviour of the lattice of these layered cathodes is that during initial charging (delithiation) electrostatic repulsion of the oxygen-containing layers occurs, with the decreasing average charge of the O-ions at the high-charge state reducing the repulsion between the layers and consequently, the inter-layer distance. Although it is generally accepted that the capacity of Li(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$ arises from the Ni$^{2+}$/Ni$^{3+}$/Ni$^{4+}$ redox centers within the 3-4 operating window, the contribution of the Mn$^{3+}$/Mn$^{4+}$ and Co$^{3+}$/Co$^{4+}$ redox couples to this capacity is also reported.\textsuperscript{30,33}

In this work, we report a Li-rich Li$_{1-x}$Mn$_2$O$_2$ (xLiMnO$_2$-(1-x)(Li$_{0.5}$Ni$_{0.5}$O$_2$)(Li$_{1/3}$Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$ composite material, $M = \text{Li, Ni, Mn, Fe}$) that is Co free. We study its electrochemical performance and function, determining the phase evolution of the active phase (Li$_{5/6}$Ni$_{1/6}$)(Li$_{1/6}$Ni$_{1/6}$Mn$_{1/3}$Co$_{1/3}$)O$_2$ using operando neutron powder diffraction (NPD). We examine the lithiation/delithiation mechanism of the active phase within a whole battery alongside the typical two-phase transitions of the graphite anode during galvanostatic charge and discharge within the 2.0 – 4.5 V window (vs. graphite), noting that the Li-rich Li$_{1/6}$MnO$_3$ component ($\sim 25$ wt.%) is electrochemically inert. By examining the oxygen positional-parameter during cycling, we establish the origin of the capacity of the (Li$_{5/6}$Ni$_{1/6}$)(Li$_{1/6}$Ni$_{1/6}$Mn$_{1/3}$Co$_{1/3}$)O$_2$ phase. Our structural study is coupled with our examination of the cathode’s performance characteristics to establish the structure-function relation of this novel cathode material.

**Experimental**

The cathode powder was synthesized using a precursor solution prepared by dissolving stoichiometric amounts of LiNO$_3$, Mn(CH$_3$COO)$_2$, Ni(CH$_3$COO)$_2$, and Fe(CH$_3$COO)$_2$ (Sigma-Aldrich) in an adequate amount of ethanol and N,N-dimethyl formamide. 20\% excess LiNO$_3$ was added to form Li$_{1/2}$(Mn$_{0.5}$Ni$_{1/3}$Fe$_{1/3}$)O$_2$. After stirring for 1.5 hr., 10 wt.% of polyvinylpyrrolidone (1,300,000 g$\cdot$mol$^{-1}$, Sigma-Aldrich) was added to the resultant solution. After overnight stirring, the precursor was dried at 100 °C for 24 hr. to evaporate solvents and then calcined at 900 °C for 2 hr. with a heating rate of 300 °C$\cdot$h$^{-1}$ in flowing oxygen to obtain the cathode powder.

The phase composition and crystallographic structure of the as-prepared cathode powder was obtained using XRPD with a GBC mini-material analyzer (U.S.A) with CuKα radiation. Morphological and particle size studies were performed using SEM with a JEOL JSM-7500 (Japan). High-resolution NPD data were collected using ECHIDNA, the high-resolution neutron powder diffractometer at the Open Pool Australian Light-water (OPAL) research reactor at the Australian Nuclear Science and Technology Organisation (ANSTO).\textsuperscript{34} The neutron beam wavelength was 1.6238(3) Å, determined using the La$^{115}$B$_4$, NIST standard reference material 660b. The NPD data were obtained in the 20 angular range 4 to 164° with a step size of 0.125°. Fullprof with visualization in WinplotR\textsuperscript{35, 36} was employed to perform Rietveld analysis of the obtained XRPD and high-resolution NPD data. The parameters including background coefficients, zero-shift, peak shape parameters, lattice parameters, the O positional parameter, and isotropic atomic displacement parameters are optimized.

A specially designed pouch-type battery was used in the collection of operando NPD data from the cathode. The cathode was prepared by casting a slurry of the cathode powder (80 wt.%), carbon black (Super P, TIMCAL, Switzerland) (10 wt.%), and polyvinylidene difluoride (PVDF) binder (10 wt.%) onto Al foil. Commercial double-side coated MCMB anodes were used as the counter electrode. The electrodes were cut into 1.5 × 7 cm strips with a coated area of 1.5 × 4.5 cm. Immobilon–P PVDF membrane (Millipore) was used as a separator due to its lower H content relative to the conventionally-used Celgard membrane, where the strong

---

2 | *Phys. Chem. Chem. Phys.*, 2014, **00**, 1-3
incoherent neutron-scattering of H is detrimental to the NPD signal. The battery was prepared by stacking 16 anode/separatore cathode assemblies with a parallel connection. The stack was placed in an Ar-filled glove box for 24 h and then wrapped in a polypropylene-coated Al foil to form a pouch. The dimension of the prepared cell was 3 cm wide (including the sealing junction of the Al pouch), 10 cm long (including electrode handles), and ~ 0.8 cm thick. Prior to the operando NPD experiment, deuterated electrolyte solution (1 M lithium hexafluorophosphate (99.99%, Sigma-Aldrich) in a 1:1 volume ratio of deuterated dimethyl carbonate (DMC) (99.5%, Novachem) to deuterated ethylene carbonate (EC) (98%, Novachem) was injected into the pouch which was heat-sealed under Ar. After 1-d of wetting, the battery was used in the operando NPD experiment. During the operando NPD experiment, the battery was cycled galvanostatically using a potentiostat/galvanostat (Autolab PG302N) at a current of 3 mA for the first two cycles and 4.5 mA for the third cycle between 2.0 and 4.5 V (vs. MCMB). Operando NPD data of the battery were collected using WOMBAT, the high-intensity neutron powder diffractometer at the OPAL research reactor at ANSTO. WOMBAT features an area detector that continuously covers 120° in 2θ and has a relatively intense neutron beam, allowing the rapid collection of data. A neutron beam with a wavelength of 2.4174(1) Å was used, determined using the LaB₆ NIST Standard Reference Material 660b. The diffractograms were obtained with an exposure time of 5 minutes per pattern in the angular range 16.1 - 136.9° in 2θ during charge-discharge cycling. The NPD data of the uncycled battery was analyzed using Fullprof with visualization in WinplotR. The refinements were performed using data in the range 35 – 120° in 2θ. Single-peak fitting of cathode 018 reflections were performed using the Large Array Manipulation Program (LAMP). Origin ver. 8.1 (OriginLab, Northampton, MA) was also used for fitting overlapping lithiated graphite reflections. The electrochemical properties of the cathode were measured using CR2032 coin-type half-cell with this cathode assembled in an Ar-filled glove box (MBraun, Germany). The electrode slurry was prepared by milling the cathode powder with carbon black (Super P, TIMCAL, Switzerland) and PVDF in a ratio 80:10:10 with N-methyl-2-pyrrolidone (Sigma-Aldrich) in a planetary mixer (Kurabo Mazerustar, Japan). Resultant slurries were coated onto an Al current collector using traditional doctor blading before being dried in vacuum at 120 °C overnight. The coin-cells were assembled using Li foil (Sigma-Aldrich, USA) as the counter electrode, polypropylene film as a separator, and 1M LiPF₆ in conventional ethylene carbonate (EC): di-ethylene carbonate (DEC) (1:1 vol.) as electrolyte. Galvanostatic cycling at various rates were performed using battery analyser (Land, China). The specific capacity (mAh·g⁻¹) that we measure is calculated for the entire composite cathode, including the Li₂MO₃ phase that is electrochemically inert within 2.0 – 4.5 V operating window.

Results and discussion

Rietveld refinement profiles using X-ray powder diffraction (XRPD) and high-resolution NPD data are shown along with scanning electron microscopy (SEM) images in Figure 1. XRPD data (Figure 1a) are modelled using a modified α-NaFeO₂ structure with the R3m space group. The R3m phase 104 reflection exhibits asymmetry and broadening that suggests a shoulder peak. Further investigation of this and other reflections unindexed by the R3m phase were able to be indexed using a C2/m space-group, which we ascribe to a Li-rich component such as Li₂MO₃ (M = Li, Ni, Mn, Fe). The ratio of the R3m phase 003 and 104 reflection intensities is determined to be 2.20, which is far from unity and indicates that the main phase is a layered structure with a high level of cation mixing, in which the (003) plane is filled with metals including Li and the (104) plane is shared by all the elements in the material. We note that splitting of the 006 and 102 as well as the 018 and 110 reflections, characteristic for the R3m layered structure, is not clearly observed due to peak broadening that likely arises from the relatively-small particle size of ~100 nm (Figure 1c) and the high level of cation mixing.
The relatively-higher sensitivity of NPD to Li in this material compared to XRPD means that the $R3m$ 104 and 018 reflections are stronger in the NPD than the XRPD data (Figure 1b) and that the Li$_3$MO$_3$ phase is more easily observed. Because of this, the final refined cathode-structure was obtained by using the NPD data. Whilst the structure of the second Li-rich C2/m phase could not be modelled using the NPD data, a Le Bail refinement of this phase was included alongside a constrained Rietveld-refinement of the main $R3m$ structure, allowing the crystallographic detail of the $R3m$ phase to be extracted as shown in Table 1 and Figure 2. The lattice parameters of the C2/m phase were determined to be $a = 4.9381(1)$, $b = 8.6386(4)$, and $c = 4.9849(2)$ Å, with $\beta = 108.872^\circ$, which differ slightly to that reported for Li$_3$MnO$_3$ where $a = 4.9292$, $b = 8.5315$, and $c = 5.0251$ Å, with $\beta = 109.337^\circ$. Importantly, the intensity of the C2/m phase reflections in the NPD differ from that simulated for the reported Li$_3$MnO$_3$, likely as a result of the partial substitution of Mn by Ni and Fe. The $R3m$ phase is found to be (Li$_{1.80(4)}$Ni$_{0.20(4)}$)(Li$_{0.0(4)}$Ni$_{0.13(4)}$Mn$_{0.33}$Fe$_{0.33}$)O$_2$ (LNMFO), in which Li atoms share the octahedral 3b site with Ni atoms, these being sandwiched between layers of hybrid Ni/Mn/FeO$_6$ octahedra. The hexagonal layered-structure of LNMFO is an O3-type, in good agreement with that reported for Li(Ni$_{0.33}$Mn$_{0.33}$Fe$_{0.33}$)O$_2$ with the major difference being the high level of Li/Ni cation mixing at both 3a and 3b sites (Figure 2). This cation mixing can complicate the electrochemical function of the cathode as the active Li intercalation layer (3b site) contains inactive Ni which may lower capacity and block Li diffusion. Nevertheless, it is the inactive Ni in this layer which is expected to increase structural stability and the subsequent cycling performance.

The high level of Li/Ni cation mixing at both 3a and 3b sites ($\chi_{3a} = 0.33$, $\chi_{3b} = 0.33$) and that the Li$_{0.50(4)}$Mn$_{0.33}(\text{Ni/Fe})_{0.17}$ phase could not be modelled using the NPD (upper) and XRPD (bottom) data.

To correlate the electrochemical performance with the structural evolution of the cathode, high-intensity NPD data of a neutron-friendly battery containing this cathode during charge...
and discharge were collected. These data are complicated by the same peak broadening affecting the high-resolution NPD data, but also from additional peaks and features in the data from the other components of the battery. Such features include a significant background from the hydrogen-containing separator and scattering from the liquid electrolyte, and reflections overlapping those of the cathode arising from the aluminum pouch. Detailed structural analysis of the cathode was therefore limited. A Rietveld refinement plot using the NPD data of the battery prior to electrochemical cycling is shown in Figure 3.

There are, as expected, four identifiable phases in the as-prepared battery, these being Al, graphite, Cu, and LNMFO. The second Li-rich phase of the cathode was not observed as a result of the significant background. The strongest LNMFO reflections in the high-resolution NPD data, the 006/012, 104, and 018/110 reflections, are identified in these high-intensity NPD data, although these are weak. During charging, these LNMFO reflections become less intense and are nearly unobservable at the charged state of the battery. Consequently, standard sequential Rietveld-refinement using the operando NPD data was difficult, and possible only using a highly-constrained model with the background and oxygen positional-parameter ($z$) the only refineable parameters, where the anode lattice was analyzed using Le Bail extraction. Rietveld analysis was also supplemented with single-peak fitting to understand the structural changes occurring to the LNMFO phase during charge/discharge cycling.

The battery voltage during the operando experiment is shown in Figure S1. During the battery formation cycle (the first), electrolyte decomposition is observed at the battery’s high charge-state (4.48 V vs. MCMB), appearing as a drop in the liquid structure-factor contribution to the pattern arising from the electrolyte (arrow in Figure S1). During the first cycle, the large irreversible-capacity of 41.2 mAh (coulombic efficiency of 51%) was obtained, which may be ascribed to the electrolyte decomposition and the formation of a solid-electrolyte interface. After the first cycle, efficiencies of 89.1% and 87.0% are observed during cycling at 3 and 4.5 mA, respectively. The calculated charge (83.25 mAh) and discharge (41.2 mAh) capacities are equivalent to 104.1 and 52.6 mAh g$^{-1}$, respectively, for total composite-cathode. The use of deuterated electrolyte with a heavier molecular-mass and higher viscosity can be detrimental to battery performance, as noted in previous work.$^{52-56}$ The incremental capacity-plot (Figure 4) exhibits features only from the couples expected to be redox-active between 3 and 4.3 V, which correspond to Ni$^{2+}$/Ni$^{3+}$ and Ni$^{3+}$/Ni$^{4+}$ transitions, respectively.$^{47}$ The absence of a peak around 3 V indicates the Mn$^{3+}$/Mn$^{4+}$ redox couple is inactive and that no or minor amounts of Mn$^{3+}$ are present in the cathode.$^{48}$ The presence of electrochemically-inactive Mn$^{4+}$ is expected to impart structural stability to the cathode, which alongside Fe$^{3+}$, also not electrochemically active in the voltage range proposed for this cathode, promote structural stability.$^{8}$

To understand the battery function in terms of structure, we first examine the graphite 002 reflection of the anode ($\sim$ 42.0° in 2θ) in the operando NPD data for the battery (Figure S1). The shift in position of the graphite 002 reflection arises from lithiation and delithiation, with the observed phase transformation agreeing well with the battery voltage-curve. Given that the anode is in excess in the battery to ensure the complete reaction of cathode, the complete lithiation of graphite to the LiC$_6$ phase is not observed, with the LiC$_6$ 001 reflection (d = 3.70 Å)$^{50}$ expected at $\sim$ 38.0° in 2θ, not appearing. Fitting of the overlapping lithiated graphite reflections with Gaussian functions reveals peak positions corresponding to that of C, LiC$_{18}$, and LiC$_{12}$ (Figure S2 and S3).$^{50}$ Based on the evolution of intensity of these peaks during charge/discharge, we note the presence of the two-phase C-

**Figure S1.** Incremental capacity-plot for the LMNFO-containing battery during the second cycle, identifying key voltages in the battery mechanism, where the black and red curves represent charge and discharge, respectively.
Li$_{18}$ and Li$_{18}$-Li$_{12}$ reactions that confirm the expected reversible lithiation of the anode. Gaussian peak-fitting of the LNMFO reflections in the operando NPD data is complicated by significant peak overlap. The contour plot of the operando data (see Figure S4 in the supporting information) reveals that the 006/012 reflections change during delithiation and lithiation. Figure 5a shows the evolution of the 2θ position of the LNMFO 006/012 reflections obtained through single Gaussian peak-fitting during charge/discharge cycling. Given the reported structural response of the $R3m$ LiCoO$_2$2,4 and Li(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)O$_2$18,29 during delithiation and lithiation, iso-structural to LNMFO, we expect the lattice parameter $c$ for LNMFO to first increase and then decrease during the battery charging. This non-Vegard change of the lattice parameter $c$ in the hexagonal-layered cathodes is ascribed to electrostatic repulsion between the O-containing layers and the subsequent deficient average-charge of the O ions (Figure 2). Interestingly, no inflection point is observed in the position of the overlapping LNMFO 006/012 reflections (Figure 5a), with the peak shifting to higher and lower angle during charge and discharge, respectively. Given the hexagonal-layered structure of the LNMFO and known lattice response of iso-structural cathodes during lithiation/delithiation,2,29 the change in the position of the LNMFO 006/012 reflections is likely dominated by that of the $c$ axis change as a result of changing Li content.31, 32 The substitution of Co by Fe is not expected to alter the electrochemistry of a $R3m$ ternary cathode, and the dissimilar lattice evolution of the LNMFO and other iso-structural cathodes must therefore be attributed to the high level of Li/Ni cation mixing in LNMFO. Given the ~ 25% inert Li$_2$MnO$_3$ phase and the specific charge capacity of 104.1 mAh g$^{-1}$ for the composite cathode during the first charge in the operando NPD experiment, we calculate a capacity of ~139 mAh g$^{-1}$ for the active LNMFO phase, which we note closely approaches that of LiCoO$_2$ (~140 mAh g$^{-1}$)2,4. For relatively equal capacity, the LNMFO exhibits a significantly smaller (~80%) change along the [00l] direction during charge/discharge compared with the LiCoO$_2$2,4, with the peak position of the LNMFO 006/012 reflections shifting by only 0.8% compared with ~4.0% for the LiCoO$_2$ 006 reflection).2,4

The LNMFO 018 and 110 reflections also overlap, and the evolution of the peak intensity of the Gaussian peak describing these is shown in Figure 5b. The contour plot of the operando data (see Figure S5 in the supporting information) reveals that the 018 and 110 reflections separate somewhat and their intensity decreases during delithiation, with the reverse occurring during lithiation. As the LNMFO 018 and 110 reflections are broad and the inter-planar spacing of these is close, single-peak fitting is used to monitor the changes of the two reflections. The LNMFO (018) and (110) planes consist of all the elements in the material (Li, Fe, Mn, Ni, and O, Figure 2). Considering that Li and Mn have negative coherent neutron-scattering lengths (-1.9 and -3.7 fm, respectively) and that Fe, Ni, and O have positive coherent neutron-scattering lengths (9.5, 10.3, and 5.8 fm, respectively), if only the population of the active Li site (3b) during charge/discharge is considered, then the intensity of the LNMFO 018/110 reflections is expected to increase and decrease during Li 3b site depopulation and population, respectively. We observe the opposite here, with the changes in the intensity of the LNMFO 018/110 reflections driven by changes in the oxygen positional-parameter. During lithiation/delithiation (reduction/oxidation), the transition-metal to oxygen bond-length changes as a result of the valence change of the redox center. Our incremental capacity-plot (Figure 4) indicates that the Ni$^{2+}$/Ni$^{3+}$/Ni$^{4+}$ is the active redox center in the LNMFO and therefore responsible for the average-valence change of the octahedral metal-sites. Table 2 summarizes the reported length of the Ni-O bond at various Ni oxidation states obtained from bond-valence summation calculations.39 The Ni-O bond in similar materials is longest at higher oxidation-states of Ni, contrary to that expected from a simple electrostatic argument.

Figure 5. (a) Evolution of the 2θ position of the Gaussian peak describing the LNMFO 006/012 reflections and (b) the evolution of intensity of the Gaussian peak describing the LNMFO 018/110 reflections, associated with the refined $z$, during charge/discharge cycling (see Figure S3 and S1 in the supporting information).

To understand further the structural response of the LNMFO during charge/discharge, the oxygen positional-parameter ($z$) was extracted using highly-constrained Rietveld refinement, and $z$ is shown alongside the intensity change of the LNMFO 018/110 peak in Figure 5b. The decrease and increase in 018/110 peak intensity are associated with the increase and decrease, respectively, of $z$. To further support this finding, simulated NPD patterns of LNMFO with various $z$ were created and the relative 018/110 peak intensity compared with that
LNMFO exhibits only a minor change in lattice, a phenomenon correlated to increasing octahedral distortion which likely assists in stabilizing the LNMFO structure.

The galvanostatic charge-discharge characteristics of the cathode were measured using coin-type half-cells between 2 and 4.5 V (vs. Li) at a current rate of 0.1 C (Figure 8a). These results indicate that the cathode delivered an initial discharge capacity of ~103 mAh.g\(^{-1}\) at 0.1 C.\(^{39,40}\) We again note that our cathode is a composite containing ~25% electrochemically-inert Li\(_2\)MO\(_4\), with the active LNMFO having a capacity ~137 mAh.g\(^{-1}\) that approaches that of LiCoO\(_2\) (~140 mAh.g\(^{-1}\)) and of Li(Mn\(_{1/3}\)Ni\(_{1/3}\)Co\(_{1/3}\)O\(_2\)) (~160 mAh.g\(^{-1}\)). We show that it is the Ni\(^{2+}/\)Ni\(^{3+}/\)Ni\(^{4+}\) redox center that contributes to the LNMFO capacity, where the Fe\(^{3+}\) and Mn\(^{4+}\) are not active in the voltage range of the battery and promote further structural stability at the expense of higher capacity.\(^{21}\) \(^{23}\) The composite cathode retains a discharge capacity of ~87 mAh.g\(^{-1}\) (116 mAh.g\(^{-1}\) for the LNMFO phase) after 100 cycles with no significant variation in the voltage plateaux of the charge-discharge curves, indicating 84% capacity retention and low electrode-polarization. Additionally, cells electrochemically-cycled over 100 times showed a coulombic efficiency of ~99% (Figure 8b). Nyquist plots (Figure S7 in the supporting information) indicate a similar charge-transfer resistance for the cathode before and after 100 cycles (~35 and ~48 \(\Omega\), respectively) with this implying facile ionic/electronic transfer kinetics.

The structure of the transition-metal oxygen octahedron with values of \(z\) associated with the measured 018/110 reflection intensity at the 0, 50, and 100% charge states of the battery (\(z = 0.258, 0.264,\) and \(0.270\), respectively) is shown in Figure 7. Changes in the oxygen position are associated with changing M-O bond length, and also with distortion of the transition-metal oxygen octahedron, represented by the oxygen-transition metal-oxygen angle. On charging to the 50% and 100% charge state, this angle increases by 3% and 6%, respectively (from 93.3\(^{\circ}\) to 96.1\(^{\circ}\) and 99.0\(^{\circ}\), respectively). During lithiation, the

Conclusions
Nano-sized Li-rich, Co-free Li$_{1+x}$MO$_2$ ($M$ = Li, Ni, Mn, Fe) for application as a lithium-ion battery cathode was prepared using a simple and direct wet-chemical method. The as-synthesized powder was characterized and found to contain predominantly (Li$_{0.80(4)}$Ni$_{0.20(4)}$)($Li_{0.20(4)}$Ni$_{0.13(4)}$Mn$_{0.33}$Fe$_{0.13}$)$_{3/2}$O$_2$, a phase with a layered $R3m$ structure and a high level of cation mixing, alongside a more minor (~25%) inert Li$_2$MnO$_3$ secondary phase. The performance characteristics of the Co-free cathode approach that of commercial and Co-containing counterparts, before optimization. We studied the structural evolution of the active (Li$_{0.80(4)}$Ni$_{0.20(4)}$)(Li$_{0.20(4)}$Ni$_{0.13(4)}$Mn$_{0.33}$Fe$_{0.13}$)$_{3/2}$O$_2$ phase using operando neutron powder-diffraction and found a lattice response that was dissimilar to iso-structural cathodes, attributable to the different level of cation mixing. We show that the capacity of this novel material comes from the Ni$^{2+}$/Ni$^{3+}$/Ni$^{4+}$ redox centers. Notably, the operando powder-diffraction results suggest excellent structural-stability of the active component, which exhibits a change of only ~0.8% (for ~139 mAh.g$^{-1}$) of the stacking axis of its layered structure, compared with the ~4% change in LiCoO$_2$ (for ~140 mAh.g$^{-1}$), a characteristic that may be exploited to enhance capacity retention of this and similar materials.
