This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Silver Nanoparticles Supported on Passivated Silica: Preparation and Catalytic Performance in Alkyne Semi-hydrogenation

DOI: 10.1039/b000000x

Herein, we report the preparation of small and narrowly distributed (2.1 ± 0.5 nm) Ag nanoparticles supported on passivated silica, where the surface OH groups are replaced by OSiMe₃ functionalities. This synthetic method involves the grafting of silver(I) bis(trimethylsilyl)amide ([AgN(SiMe₃)₂]⁺) on silica partially dehydroxylated at 700 °C, followed by a thermal treatment of the grafted complex under H₂. The catalytic performance of this material was investigated in the semi-hydrogenation of propyne and 1-hexyne and compared to that of 2.0 ± 0.3 nm Ag nanoparticles supported on silica. Whilst surface passivation slightly decreases the activity in both reactions (by a factor 2-3), probably as the result of a decreased alkyne adsorption properties or the presence of less accessible active sites on the passivated support, the AgNP@SiO₂ catalysts demonstrate a remarkable selectivity for the production of alkenes.

Introduction

Controlling the size, shape and composition of supported metal nanoparticles has been a vibrant field of research for more than 100 years, in view of their critical impact on many industrial processes. An important aspect of these supported catalysts is the interface between the nanoparticles and the support. In fact, adjusting adsorption properties whilst keeping the same support can affect both the activity and the selectivity of a catalyst by altering the active sites and/or their surroundings. For instance, it has been shown that the replacement of surface hydroxyl groups by trimethylsilyl functionalities (surface passivation) has a positive effect on the catalytic performances of single-site catalysts, e.g., Ti-based epoxidation catalysts, Ta-based silica-supported epoxidation catalysts and Re-based alumina-supported metathesis catalysts. Moreover, passivation effects have also been observed for supported nanoparticle catalysts, such as Au nanoparticles supported on passivated silica, which outperform the alternative titania–supported gold catalyst in the aerobic epoxidation of stilbene. In addition, surface passivation can provide mechanistic clues to the role of the OH groups of the support in metal catalysis. In fact, Au nanoparticles supported on passivated silica require H₂ to oxidise CO with O₂, while this reaction takes place with or without H₂ on Au nanoparticles supported on hydroxylated silica, suggesting that the proton of the OH group can provide surface Au–H hydrides.

The catalytic activity of Ag nanoparticles towards a variety of hydrogenation reactions has been shown previously. We recently investigated the gas-phase semi-hydrogenation of propyne, an industrially relevant reaction for the purification of olefin streams, using silica–supported Ag nanoparticles. Whilst various alkyne semi-hydrogenation catalysts have been developed, noteworthy was the very high alkene selectivity (ca. 90%) at a high degree of alkyne conversion for our Ag catalyst. This study revealed that the selective character of Ag stems from the unique mechanism, which occurs on Ag surfaces. Namely, in contrast to most metals for which hydrogenation takes place via the classical Horiiuti–Polanyi mechanism (dissociation of H₂ on the metal surface followed by sequential H addition), the key elementary step for the Ag catalysed reaction is the direct activation of H₂ on the chemisorbed alkyne, probably at B5 step sites. One of the major problems in the catalytic semi-hydrogenation of alkynes is the production of green-oil, an oligomeric by-product, which can cause catalyst deactivation and equipment blockage. Interestingly, it has been shown for the related Pd-based supported alkyne hydrogenation catalysts that the support itself has a large influence over the formation of such by-products. With this in mind, and in view of the dramatic effect of surface passivation on the catalytic activity of silica-supported Au nanoparticles, we have investigated the effect of surface passivation on the activity and selectivity of silica–supported Ag nanoparticles in the semi-hydrogenation of alkynes. Particularly, we report the catalytic performance in the semi-hydrogenation of propyne and 1-hexyne on Ag nanoparticles supported on passivated silica prepared via the controlled reaction of [AgN(SiMe₃)₂] with SiO₂700 and thermal treatment under H₂ (Scheme 1).
Results & Discussion

The reaction of an excess of \([\text{AgN(SiMe}_3\text{)}_2]\)_4 (2 equiv. Ag per surface silanols) in a 1:1 pentane:dichloromethane mixture with SiO\(_2\)-700 led to a white solid, Ag(I)@SiO\(_2\), which was characterised by elemental analysis, IR spectroscopy and solid-state NMR spectroscopy. During this step, all surface silanols are consumed as evidenced by the disappearance of the SiO-H band, at 3745 cm\(^{-1}\), in the IR spectrum (Figure 1a) accompanied by the appearance of C-H bands at 2897, 2952 and 1400 cm\(^{-1}\). This data is consistent with the chemical grafting of \([\text{AgN(SiMe}_3\text{)}_2]\)_4 on the silanol groups of the silica surface. \(^1\)H magic angle spinning (MAS) solid-state NMR confirms the total consumption of silanols as evidenced by the absence of a SiO-H peak at 1.8 ppm (Figure S1), while a single proton environment at 0 ppm indicates surface ligands. Furthermore, the \(^{13}\)C High-Power DECoupled (HPDEC) MAS NMR spectrum two distinguishable SiMe\(_3\) groups are observed at 0 and 6.5 ppm, indicating that there are two types of trimethylsilyl groups present associated with O-Si(CH\(_3\))\(_3\) and N-(Si(CH\(_3\))\(_2\))O functionalities respectively (Figure S2).\(^{33, 34}\) The relatively intensity of these peaks give a O-Si(CH\(_3\))\(_3\):N-Si(CH\(_3\))\(_3\) ratio of ca. 1:4. This assignment is corroborated by \(^29\)Si cross-polarisation (CP) MAS NMR spectroscopy, with the observation of two peaks at 3 and 14 ppm corresponding to Ag-N(SiMe\(_3\))\(_2\) and O-SiMe\(_3\) surface species respectively (Figure 1b). It is noteworthy that this solid contains 4.4 wt% of Ag, corresponding to 1.2 Ag nm\(^{-2}\) (1.6 Ag per SiOH), which exceeds the initial OH density. In addition, N elemental analysis results of 0.69 wt% suggests that the ratio of Ag:N is nearly constant (1:1.2). Furthermore, in view of the presence of O-Si(CH\(_3\))\(_3\), which results from the subsequent reaction of HN(Si(CH\(_3\))\(_3\))\(_2\)^{35} released upon the reaction of the surface silanol with [AgN(SiMe\(_3\))\(_2\)]\(_4\), there is a clear indication for the formation of multinuclear Ag species. The ratio of OSiMe\(_2\)-to-N(SiMe\(_3\))\(_2\) of 1:3.7 and the presence of 1.2 Ag nm\(^{-2}\) determined by elemental analysis are consistent with the formation of OSiMe\(_2\) (0.5 per nm\(^{-2}\)) and Ag species present as tetraneutral species in the molecular precursor. The proposed surface species, noted as Ag(I)@SiO\(_2\) in Scheme 1, is grafted through one O-Ag linkage (0.3 per nm\(^2\)). In fact, the formation of multinuclear species was previously observed in the grafting of a tetra-nuclear \([\text{Cu(OTBu)}\text{]}_4\) and \([\text{Cu(OSi(OtBu)}\text{]}_4\) species and assigned to linearly arranged Cu at the surface.\(^{36}\)

Figure 1: a) IR spectrum of SiO\(_2\)-700, Ag(I)@SiO\(_2\) and AgN(SiMe\(_3\))\(_2\)-TMS and b) \(^{29}\)Si CPMAS (5 KHz, 400 MHz, ns = 51200) NMR of Ag(I)@SiO\(_2\) and AgN(SiMe\(_3\))\(_2\)-TMS.

Treatment of Ag(I)@SiO\(_2\) with H\(_2\) (0.5 bar) at 300 °C for 20 h yields an homogeneous dark orange solid. Transmission electron microscopy of the sample exposed to air shows the presence of nanoparticles having an average diameter of 2.1 nm with narrow size distribution of 0.5 nm (Figure 2), which corresponds to a dispersion of ca. 55% assuming the particles have a cuboctahedral shape.\(^{37}\) IR spectroscopy of this material, AgN(SiMe\(_3\))\(_2\)-TMS, shows that silanol functionalities are not regenerated upon H\(_2\) treatment (absence of a peak at 3745 cm\(^{-1}\)) while the trimethylsilyl groups remain, as evidenced by the C-H bands at 2964 and 2906 cm\(^{-1}\). Note however the presence of new bands at 3300-3500 cm\(^{-1}\) attributed to N-H vibrations (Figure S3), resulting from the hydrogenolysis of the AgN(SiMe\(_3\))\(_2\) species and the probable incorporation of NH\(_2\) into the silica surface.\(^{38}\) Additionally, the C-H bands have decreased by comparison with Ag(I)@SiO\(_2\), suggesting that some of these species have been removed upon H\(_2\) treatment. The \(^{29}\)Si CPMAS spectrum of AgN(SiMe\(_3\))\(_2\)-TMS displays a single peak at 14 ppm (Figure 1b), consistent with the sole presence of O-SiMe\(_3\) surface functionalities and indicating that “Ag-\(\text{N(SiMe}_3\text{)}\)\(_2\)” moieties of Ag(I)@SiO\(_2\) have been fully converted upon H\(_2\) treatment. In view of the formation of Ag-nanoparticles, SiO-Ag bonds are probably cleaved by H\(_2\) to regenerate SiOH and provide Ag(0), which leads to the formation of the nanoparticles. It is likely that the thus-formed SiOH reacts with the released HN(SiMe\(_3\))\(_2\) leading to a surface covered with OSiMe\(_2\) species and Ag nanoparticles. This process is reminiscent of what has been observed in the formation of nanoparticles from the analogous gold complex.\(^{15}\)
The catalytic performance of Ag$_{2}$SiO$_{2}$TMS was first evaluated in the semi-hydrogenation of propyne. Firstly, the selectivity of Ag$_{2}$SiO$_{2}$TMS towards propene formation was tested as a function of propyne conversion (Figure 3a). Ag$_{2}$SiO$_{2}$TMS maintains a high selectivity (87 - 93%) for the formation of propene over a broad range of propyne conversions (10 - 100%). Also noteworthy is the constant and low selectivity of this catalyst towards propane and oligomers as previously observed for Ag nanoparticles supported on hydroxylated silica.\textsuperscript{22} To determine the effect of surface passivation on this reaction, these results were compared to 1 wt% Ag 2.0 ± 0.3 nm Ag nanoparticles supported on silica (57% dispersion), having surface silanols.\textsuperscript{22} It is noteworthy that preparation of this material, Ag$_{2}$SiO$_{2}$OH, with a higher Ag wt% loading resulted in considerably larger Ag particles.\textsuperscript{22} At 20% propyne conversion, the propene selectivity of both catalysts is high; Ag$_{2}$SiO$_{2}$TMS shows an improvement with a value of 94% in comparison to 86% for Ag$_{2}$SiO$_{2}$OH (Figure 3b). However, at 75% propyne conversion, the selectivity of both catalysts is similar (ca. 90%), see Figure S5) indicating that secondary processes are not affected by the surface functionalities.

Figure 3: a) Selectivity-conversion relationship for Ag$_{2}$SiO$_{2}$TMS to propene (red circles), propane (blue squares) and oligomers (green triangles). Activity and selectivity of Ag$_{2}$SiO$_{2}$TMS and Ag$_{2}$SiO$_{2}$OH at 20% conversion in (b) the gas-phase hydrogenation of propyne and (c) liquid-phase hydrogenation of 1-hexyne.

In addition, the rate of reaction over Ag$_{2}$SiO$_{2}$TMS at 20% propyne conversion, is ca. 2.5 times lower than that of Ag$_{2}$SiO$_{2}$OH (0.78 mmolC$_{3}$H$_{6}$s$^{-1}$molAg$^{-1}$ vs. 2.1 mmolC$_{3}$H$_{6}$s$^{-1}$molAg$^{-1}$, respectively), while the activity expressed per gram of catalyst favours Ag$_{2}$SiO$_{2}$TMS over Ag$_{2}$SiO$_{2}$OH (1.7 mmolC$_{3}$H$_{6}$s$^{-1}$g$^{-1}$ vs. 1.1 mmolC$_{3}$H$_{6}$s$^{-1}$g$^{-1}$, respectively), because of the higher Ag loading (ca. 4 times) in Ag$_{2}$SiO$_{2}$TMS. A similar activity trend was also observed in the three-phase fully selective (>99%) semi-hydrogenation of 1-hexyne (Figure 3c). This decrease in activity is not due to a difference in particle sizes, which are similar (2.1 ± 0.5 nm for Ag$_{2}$SiO$_{2}$TMS vs. 2.0 ± 0.3 nm for Ag$_{2}$SiO$_{2}$OH) and do not increase during the catalytic tests (Figure S6). The lower activity for the semi-hydrogenation of propyne may be due to differences in reactant adsorption, or to the presence of less accessible active sites as a result of surface passivation in Ag$_{2}$SiO$_{2}$TMS. To further elucidate the origin of this difference in activity, the adsorption of H$_{2}$ and propyne was measured (Figure S7 and S8 respectively). Adsorption measurements showed that both catalysts adsorb negligible amounts of H$_{2}$ at 290 mbar and 0 °C (0.002 ± 0.003 and 0.005 ± 0.003 mmolH$_{2}$ sample$^{-1}$ for Ag$_{2}$SiO$_{2}$TMS and Ag$_{2}$SiO$_{2}$OH, respectively, < 0.02 H per Ag$_{24}$OH sample). Moreover, propyne adsorption is found to be slightly lower for the passivated catalyst, with 0.90 ± 0.02 vs. 0.96 ± 0.04 mmolC$_{3}$H$_{4}$ sample$^{-1}$ for Ag$_{2}$SiO$_{2}$TMS and Ag$_{2}$SiO$_{2}$OH, respectively. However, this difference is particularly striking when the adsorption is expressed in mmol of adsorbed propyne per mmol surface Ag: 18 mmolC$_{3}$H$_{4}$ molAg$^{-1}$ for Ag$_{2}$SiO$_{2}$OH vs. 4 mmolC$_{3}$H$_{4}$ molAg$^{-1}$ for Ag$_{2}$SiO$_{2}$TMS. This decrease in propyne adsorption on Ag$_{2}$SiO$_{2}$TMS may be due to the change in support surface functionalisation and/or density effects due to the increased Ag loading on the Ag$_{2}$SiO$_{2}$TMS sample. Since the rate-determining step for the hydrogenation of propyne on Ag nanoparticles is associated with the dissociation of H$_{2}$ on adsorbed propyne,\textsuperscript{22} the difference in reactivity between the two catalysts could originate from the decreased adsorption of the alkyn on Ag$_{2}$SiO$_{2}$TMS, the higher density of particles or a decreased amount of active sites as a result of passivation of the silica surface.

**Conclusions**

Using surface organometallic chemistry, we have prepared small Ag nanoparticles (2.1 ± 0.5 nm) supported on passivated silica, through the controlled reaction of the partially dehydroxylated support with silver(I) bis(trimethylsilyl)amide to form well-defined silica-supported Ag(I) bis(trimethylsilyl)amide tetranuclear clusters, as well as surface SiMe$_{3}$ groups. These species are then decomposed to form nanoparticles by a controlled H$_{2}$ treatment. The small size and narrow distribution of the Ag particles prepared by this route is particularly important considering the high Ag weight loading (4.4 wt%). These supported Ag nanoparticles display very good selectivity (ca. 90%) for the semi-hydrogenation of propyne, even at high propyne conversion. These results suggest that, in this case, the surface OH functionalities do not take part in the semi-hydrogenation of propyne, as the selectivity towards propene remains remarkably highly independent of support passivation. However, this modification of the support surface results in a decrease in reaction rate (by a factor of ca. 2-3), possibly due to a decrease in the number of adsorbed propyne molecules per surface Ag for the Me$_{3}$Si-functionalised support; yet as a result of much higher loading the activity of the catalyst is ca. twice higher per gram of catalysts. We are currently further exploring the effect of surface functionalities in controlling the catalytic activity and selectivity of supported metal nanoparticles.
Experimental

General

All experiments were conducted under argon atmosphere using standard Schlenk and glove-box techniques unless otherwise stated. Solvents were dried over an alumina column (MB SPS-800, MBraun), stored over 4Å molecular sieves and degassed before use. H₂ (99.999%) was purchased from PanGas and propyne (99%) was supplied by Sigma-Aldrich. 1-hexyne was purchased from Acros Organics (98%). IR measurements were performed using a Bruker Alpha-T FTIR spectrometer inside an argon-filled glove-box. Samples were pressed into a self-supporting disk for acquisition using a manual press. NMR spectroscopy was conducted using a 400 MHz Bruker spectrometer. Elemental analysis was conducted at Pascher Analytical Labor in Germany. TEM images were collected with a Philips CM12 Transmission Electron Microscope.

Preparation of [AgN(SiMe₃)₂]₄. [AgN(SiMe₃)₂]₄ was prepared according to a modified literature procedure: 31, 39 Equimolar amounts of silver(I) trifluoromethanesulfonate and lithium bis(trimethylsilyl)amide were reacted in Et₂O at room temperature for 16 h in the absence of light. After extraction with pentane and recrystallisation, silver(I) bis(trimethylsilyl)amide was isolated as colourless crystals in 15% yield. ¹H NMR (300 MHz, CD₂Cl₂); δ = 0.29 ppm. ¹³C CPMAS (10 kHz, 400 MHz); δ = 4.04 ppm. ³¹P CPMAS (10 kHz, 400 MHz); δ = 8.6 ppm. ²⁹Si CPMAS (10 kHz, 400 MHz); δ = 2.8 ppm.

Preparation of SiO₂-700. Silica partially dehydroxylated at 700 °C (SiO₂-700) was prepared by calcination of compacted Aerosil Degussa (200 m²·g⁻¹) at 500 °C for 14 h followed by a treatment under vacuum (10⁻⁵ mbar) at 700 °C for 5 h (heating rate of 5 °C·min⁻¹ from 500 to 700 °C); 0.26 mmol SiO₂·g⁻¹, 0.8 OH·nm⁻¹. ⁴¹Si MAS NMR spectra of Ag(I)@SiO₂-700 (0.5 g, 0.13 mmol SiO₂, 1 equiv.) was contacted with a 1:1 pentane/dichloromethane solution of [AgN(SiMe₃)₂]₄ (0.073 g, 0.26 mmolAg, 2 Ag equiv. per SiO₂) for 3 h at room temperature in the absence of light. After washing 3 times with fresh solvent and drying under high vacuum a white solid, Ag(I)@SiO₂ was obtained. IR (disk) = 2897, 2952, 1980, 1863, 1629, 1400 cm⁻¹. ¹H MAS (10 kHz, 400 MHz); δ = 0 ppm. ¹³C CPMAS (10 kHz, 400 MHz); δ = 0.0, 6.5 ppm. ²⁹Si CPMAS (10 kHz, 400 MHz); δ = 3 and 14 ppm. Elemental analysis; Ag = 4.4, C= 2.3, H = 0.6 and N = 0.7 wt%.

Preparation of Ag₈NP@SiO₂-700. Ag₈NP was treated with H₂ (500 cm³, 0.5 bar, 100 H₂:Ag₈); dried over R3-11 G (T5 x 3 mm) BASF catalyst and 4Å molecular sieves and heated with a rate of 5 °C·min⁻¹ and held at 300 °C for 20 h. After cooling, the H₂ atmosphere was removed using ultra-high vacuum techniques. This treatment yielded a dark orange powder. TEM imaging of the solid showed nanoparticles were present on the support surface with an average diameter of 2.1 ± 0.5 nm. ²⁹Si CPMAS (10 kHz, 400 MHz); δ = 14 ppm. Elemental analysis; Ag = 4.3, C = 1.9, H = 0.5 and N = 0.3 wt%.

Preparation of Ag₈NP@SiO₂-413. This sample was prepared according to a reported procedure. 22 Selective hydrogenation of alkynes. The gas-phase hydrogenation of propyne was carried out in a continuous-flow fixed-bed micro-reactor (12 mm i.d.) equipped with an on-line gas chromatograph (Agilent GC7890A), in the absence of internal and external mass transfer limitations (Figure S4). 41 Unless otherwise stated, the reactions were performed with 0.2 g of catalyst (particle size = 0.2-0.4 mm), at T = 200 °C, P = 1 bar, H₂/H₂O/H₄ = 25. The contact time, τ, was varied between 0.01 and 1 s when assessing the influence of conversion on product distribution and was kept at a value of 0.07 s (alkyne conversion = 20%) when comparing catalyst performance. The three-phase hydrogenation of 1-hexyne was carried out in a flooded-bed micro-reactor. 41 The reactant solution contained 1 vol.% of 1-hexyne, 1 vol.% of benzene (Sigma-Aldrich, >99.5%) as internal standard, and 98 vol.% of toluene (Acros Organics, 99.9%) as solvent. The hydrogenation was conducted with 0.2 g of catalyst, at T = 313 K, P = 60 bar, F(H₂) = 60 cm³·min⁻¹, and F(liquid) = 0.3 cm³·min⁻¹. The liquid at the reactor outlet was analysed offline with a gas chromatograph (HP 6890) equipped with a HP-5 capillary column and a flame ionization detector. In all cases, the conversion of the alkylne was determined as the amount of reacted alkyned divided by the amount of alkyned at the reactor inlet. The selectivity to the alkene/alkane was calculated as the quantity of alkene/alkane formed divided by the amount of converted alkyned. The selectivity to oligomers were determined as Sₜₙₜ = 100 – Sₐlkenₜₜ – Sₐlkanₜₜ.

H₂ and propyne adsorption measurements. Adsorption measurements were conducted using a BELSORP-Max instrument from BEL Japan Inc. Around 0.1 g of each catalyst was pre-treated in flowing H₂ at 200 °C with a heating ramp of 5 °C·min⁻¹ for 30 min, followed by evacuation for 3 h at the same temperature. Adsorption measurements were performed using hydrogen and propyne at 0 °C. Langmuir isotherms, non-dissociative, were fitted to the experimental results for propyne adsorption leading to the amount of gas adsorbed per surface metal. In view of the low amount of H₂ adsorbed on both catalysts, it was not possible to fit dissociative Langmuir isotherms and therefore the results reported here correspond to the amount of H₂ adsorbed at 290 mbar.
