This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
A Novel Fe/Fe$_3$O$_4$/N-carbon composite with hierarchical porous structure and in situ formed N-doped graphene-like layers for high-performance lithium ion batteries†

Yao Li$^{a}$, Qing Meng$^{b}$, Shen-min Zhu$^{*a}$, Zeng-hui Sun$^{a}$, Hao Yang$^{a}$, Zhi-xin Chen$^{b}$, Cheng-ling Zhu$^{a}$, Zai-ping Guo$^{b}$ and Di Zhang$^{*a}$

A Fe/Fe$_3$O$_4$/N-carbon composite consisting of porous carbon matrix containing a highly conductive N-doped graphene-like network and Fe/Fe$_3$O$_4$ nanoparticles was prepared. The porous carbon has hierarchical structure which inherits from rice husk and N-doped graphene-like network formed in situ. When used as an anode material for lithium batteries, the composite delivered a reversible capacity of approximately 610 mAh g$^{-1}$ at a current density of 200 mA g$^{-1}$ even after 100 cycles, due to the synergism between the unique hierarchical porous structures, highly electric conductive N-doped graphene-like networks and nanosized particles of Fe/Fe$_3$O$_4$. This work provides a simple approach to prepare N-doped porous carbon activated nanoparticle composite which could be used to improve the electrochemical performance of lithium ion batteries.

1. Introduction

Lithium ion batteries (LIBs) have been extensively used in portable electronic devices as well as electric vehicles, because of their high energy density, long cycle life, low self-discharge and no “memory effect”. As an essential part of LIBs, anode materials play an important role in the performance of LIBs and thus attract considerable attention. Accordingly, a variety of new anode materials, such as carbon materials, metal alloy, metal oxides, has been developed. Among them, iron oxide is considered as an ideal anode material since its adequate theoretical capacity (1004 mA h g$^{-1}$ for α-Fe$_2$O$_3$ and 924 mA h g$^{-1}$ for Fe$_3$O$_4$), low toxicity, moderate volume change during lithium extraction and insertion processes. However, iron oxide will break into small metal clusters since they can react with Li to form Li$_2$O, which along with a great volume expansion and a destruction of the structure upon electrochemical cycling, especially at high rates, thus resulting in severe loss of capacity with cycling and a poor electronic conductivity.

Both nanostructure design and composite with porous carbon are useful strategies to improve the reversible capacity and rate capacity. Nanostructure can shorten Li ion insertion/extraction pathways. Composite with porous carbon may buffer volume expansion upon lithium extraction and insertion. Unfortunately, porous carbons involved in the formation of composite are usually amorphous. Their low electronic conductivity has to be considered seriously, especially in LIBs system. In order to improve the electronic conductivity, attempts such as introducing graphene-like structures in porous carbon have been made. A graphitized mesoporous carbon produced by CVD has shown a high capacity of about 340 mAh g$^{-1}$ at a rate of 0.1C. The capacity of ~250 mAh g$^{-1}$ was retained after ten cycles. Similarly, a simple catalyzed method was developed for the synthesis of Fe$_3$O$_4$/graphitized mesoporous carbon composites, which showed a decent capacity of approximately 623 mAh g$^{-1}$ as well as cycling stability. In addition, nitrogen-doping is proved to be another effective way to enhance the electrochemical properties of carbon composites. Nitrogen-doped
carbonaceous materials may offer more active sites and enhance the interaction between carbon and lithium and thus to improve the kinetics of lithium diffusion and transfer.\textsuperscript{17} Nitrogen-doped graphene reported in the literature showed an energy density of approximately 199 mAh g\textsuperscript{-1} even under a high current density of 25 A g\textsuperscript{-1}.\textsuperscript{18} The incorporation of a carbon material with a porous structure, graphene-like layers, and nitrogen-doping is proposed as a feasible way to improve the electrochemical performance of iron oxides for high performance LIBs.

In this paper, Fe/Fe\textsubscript{3}O\textsubscript{4} nanoparticles were embedded into nitrogen doped porous carbon through a simple impregnation then polymerization and calcinations route, generating a novel Fe/Fe\textsubscript{3}O\textsubscript{4}/carbon composite (Fe/Fe\textsubscript{3}O\textsubscript{4}/N-carbon). The composite is composed of Fe/Fe\textsubscript{3}O\textsubscript{4} nanoparticles and porous carbon with N-doped graphene-like structure. Owing to the high specific capacity of Fe\textsubscript{3}O\textsubscript{4}, buffering effective provided by nanostructure and porous carbon composition and the improved electrical conductivity of the electrode by the incorporation of Fe nanoparticles and N-doped graphene-like structure, this Fe/Fe\textsubscript{3}O\textsubscript{4}/N-carbon showed an enhanced specific capacity and cycling stability.

2. Experimental

2.1 Preparation

Typically, a rice husk precursor was used to fabricate porous carbon (RHC) via carbonization at 650 °C, followed by activation at 800 °C by KOH. Then, the calcined RHC was washed with 12% HCl and distilled water. Washed RHC (0.5 g) was mixed with 1 mL 0.9 M iron chloride (FeCl\textsubscript{3}) solution. The mixture was exposed in pyrrole vapor at 50 °C for 3 hours, followed by calcination at 850 °C for 2 hours under nitrogen. The product is denoted as Fe/Fe\textsubscript{3}O\textsubscript{4}/N-carbon. For comparison, the mixture of RHC and iron chloride was treated by the same procedure but without pyrrole vapor exposure. The product fabricated is denoted as Fe/Fe\textsubscript{3}O\textsubscript{4}/carbon, the pure iron chloride was treated by the same procedure is denoted as Fe/Fe\textsubscript{3}O\textsubscript{4}/N.

2.2 Characterization

Fourier transform-infrared measurements (FT-IR) were conducted on KBr pellets with a PE Paragon 1000 spectrophotometer. The synthesized samples were characterized by X-ray diffraction (XRD) on a RigakuD/\textsubscript{max} 2550VL/PC system operated at 35 kV and 200 mA with Cu K\textsubscript{\alpha} radiation (\(\lambda=1.5406\) Å), at a scan rate of 5° min\textsuperscript{-1} and step size of 0.02°. Raman spectroscopy was measured on a Renishaw via Raman Microscope. X-ray photoelectron spectra (XPS) were collected on a physical electronics PHI5400 using Mg K\textsubscript{\alpha} radiation as X-ray source. All the spectra were corrected with C1s (285.0 eV) band. Elemental analysis was processed using a Vario ELIII/I sopperme isotope ratio mass spectrometer. Nitrogen adsorption measurements at 77 K were performed using an ASAP2020 volumetric adsorption analyzer, after the samples had been out gassed for 8 h in the degas port of the adsorption apparatus. Scanning electron microscopy (SEM) was performed on a JEOL JSM-6360LV field emission microscope at 15 kV. Transmission electron microscopy (TEM) was carried out on a JEOL 2020 microscope at 200 kV. Thermal gravimetric analysis (TGA) was conducted on a PE TGA-7 instrument with 20 °C min\textsuperscript{-1}.

2.3. Electrochemical measurements

Electrochemical experiments were carried out in two-electrode Swagelok cells. The working electrodes were made by mixing the Fe/Fe\textsubscript{3}O\textsubscript{4}/N-carbon composite with carbon black and binder (polyvinylidene fluoride, PVDF) at a mass ratio of 80:10:10. The mixture was then spread uniformly onto a copper foil cylinder with a diameter of 12 mm and dried in vacuum at 80 °C. The net mass loading of activated material for each tested electrode was between 1.0-1.5 mg. The cells were assembled in an argon filled glove box (Mikrouna 1220/750). Metallic lithium foil was used as the counter electrode. The electrolyte was made of 1 M LiPF\textsubscript{6} dissolved in the mixture of ethylene carbonate (EC) and diethylene carbonate (DEC) with the volume ratio of 1:1. The charge/discharge profiles of the electrodes were collected on a physical electronics CHI 660D electrochemical workstation in the potential range of 0.05-3.0 V at a scan rate of 0.5 mV s\textsuperscript{-1}. Electrochemical impedance spectra were measured by using a Chenhua CHI 660D electrochemical workstation with an AC voltage signal of 5 mV, in the frequency range between 100 kHz and 5 mHz. For comparison, the electrochemical performances of Fe/Fe\textsubscript{3}O\textsubscript{4}/carbon were evaluated under the same conditions. The cells were disassembled in the glovebox after 100 cycles, and the working electrode was taken out and washed three times using dimethyl carbonate (DMC) solution. It was then prepared for TEM observation.

3. Results and Discussion

Scheme 1 Schematic illustration of the formation of the Fe/Fe\textsubscript{3}O\textsubscript{4}/N-carbon composite.
In this work, a Fe/Fe₃O₄/N-carbon composite was synthesized by a three-step method as described in Fig. 1. Firstly, porous carbon fabricated from rice husk (RHC) was pretreated by nitric acid and carboxyl RHC was obtained. Then, the carboxyl RHC was impregnated in a FeCl₃ solution, and set in a pyrrole vapour environment at 50 °C for 3h, during which pyrrole migrated into the pores of carboxyl RHC and in situ polymerization of pyrrole occurred due to the catalytic effect of Fe³⁺ species attached on the surface of RHC at a high temperature of 850 °C generates the body-centered cubic Fe. Using the Scherrer formula from the width of the diffraction peak at 35.4°, the average size of Fe₃O₄ particles was estimated to be approximately 45 nm. The XRD pattern of Fe/Fe₃O₄/N-carbon is similar to that of Fe/Fe₃O₄/N-carbon and Fe/Fe₃O₄ particles are also present in Fe/Fe₃O₄/N-carbon.

The presence of nitrogen in the Fe/Fe₃O₄/N-carbon composite was investigated by using FT-IR (Fig. 2). The FT-IR spectrum of carboxyl RHC, shows an absorption at 1714 cm⁻¹ which is characteristic of C=O stretching vibration, owing to the existence of COOH and an absorption at 1573 cm⁻¹ which is attributed to asymmetric -COO- stretching. After calcination, the peak from COOH groups disappeared as evidenced by the spectra of both Fe/Fe₃O₄/N-carbon and Fe/Fe₃O₄/N-carbon. As compared with Fe/Fe₃O₄/N-carbon, Fe/Fe₃O₄/N-carbon has two new absorptions: (i) at 1585 cm⁻¹, attributed to N-H in-plane deformation vibrations or C=C stretching vibration, and (ii) at 1384 cm⁻¹ which is caused by the presence of C-N stretching vibration in Fe/Fe₃O₄/N-carbon composite. These two extra absorption peaks clearly suggested the presence of nitrogen in Fe/Fe₃O₄/N-carbon.

Raman spectra of RHC, Fe/Fe₃O₄/N-carbon and Fe/Fe₃O₄/N-carbon were shown in Fig. S1†). Two bands at around 1590 and 1336 cm⁻¹ are known as the graphite sp² (E₂g) carbon band or G band and the defect sp² carbon band or D band respectively. For RHC, the D band is significantly higher than the G band: I_D/I_G>1, indicating that the high content of the amorphous carbon. The I_D/I_G decreased significantly in Fe/Fe₃O₄/N-carbon and Fe/Fe₃O₄/N-carbon samples in comparison to that of RHC, indicating the graphitization in both Fe/Fe₃O₄/N-carbon and Fe/Fe₃O₄/N-carbon samples. It should be noted that no band shift was detected for Fe/Fe₃O₄/N-carbon in comparison with RHC. However, a distinct G band p-shift of 12 cm⁻¹ was observed for the sample of Fe/Fe₃O₄/N-carbon, which could be explained by the N-doping of the composite, as reported by others.
The composition of Fe/Fe₃O₄/N-carbon was further investigated by XPS measurement. As expected, all the peaks present in the spectrum (Fig. 3a) can be assigned to carbon (C 1s), nitrogen (N 1s), iron (Fe 2p³) and oxygen (O 1s). There are two binding energy peaks in the N 1s pattern (Fig. 3b). The peak at 397.8 eV is assigned to sp² hybridized N atoms bonded to carbon atoms, and that at 400.2 eV corresponds to pyrrolic N atoms trigonally bonded with sp² or sp³ hybridized carbon atoms. The XPS analyses confirm the existence of pyrrolic nitrogen in the porous composite and are consistent with the C 1s spectrum (Fig. 3c).

Nitrogen adsorption/desorption was conducted to characterize the porous structures (Fig. 4). The specific surface area of the RHC matrix and Fe/Fe₃O₄/carbon are approximately 1245 and 1116 m² g⁻¹, respectively, suggesting that the impregnation and calcination give little effect on the surface area. More interestingly the resultant Fe/Fe₃O₄/N-carbon still has a surface area of 1151 m² g⁻¹ (Fig. 4), indicating the existence of pyrrole vapor did not influence the porous structures. All the samples show a hysteresis loop in the P/P₀ range of 0.45-1.0, and the pore width was around 3.9 nm. The results clearly suggest that the large specific surface area and hierarchical microstructures of RHC were retained in Fe/Fe₃O₄/N-carbon and Fe/Fe₃O₄/carbon. These hierarchical structures would provide a buffering room for volume change and necessarily accessible channels for charge transfer during charge-discharge cycles.

The microstructures of Fe/Fe₃O₄/N-carbon and RHC were compared in Fig. 5. The porous and hierarchical structure of RHC matrix is clearly revealed in the secondary electron images given in Figs. 5a and b. The hierarchical structure of RHC was retained in the sample of Fe/Fe₃O₄/N-carbon as shown in Figs. 6c and d. Obviously, the iron oxide nanocomposite existed homogeneously on the porous carbon matrix in Fe/Fe₃O₄/N-carbon and Fe/Fe₃O₄/carbon. As determined by thermogravimetric analysis (TGA) (Fig. S2†), the weight of Fe/Fe₃O₄/N was increased during the thermogravimetric analysis since the oxidation process of Fe and Fe₃O₄ to Fe₂O₃. Depend on the mass increased ratio of 8 wt.%, the weight percentages of Fe and Fe₃O₄ are calculated as 88.5 wt.% and 11.5 wt.% in Fe/Fe₃O₄/N, respectively. Thus, the mass residual of Fe/Fe₃O₄/N-carbon and Fe/Fe₃O₄/carbon being 26 wt.% and 30 wt.%, means carbon content in Fe/Fe₃O₄/N-carbon and Fe/Fe₃O₄/carbon is around 76 wt.% and 72 wt.%, respectively.

Fig. 7 (a) CV curves of Fe/Fe$_3$O$_4$/N-carbon, (b) Capacity versus cycle number plots of Fe/Fe$_3$O$_4$/N-carbon, RHC and Fe/Fe$_3$O$_4$/carbon in the voltage range of 0.1-3.0 V at a current density of 200 mA g$^{-1}$. (c) Rate capability of Fe/Fe$_3$O$_4$/N-carbon, RHC and Fe/Fe$_3$O$_4$/carbon. (d) Nyquist plots of Fe/Fe$_3$O$_4$/N-carbon, Fe/Fe$_3$O$_4$/carbon and RHC obtained by applying a sine wave with an amplitude of 5.0 mV over the frequency range from 100 kHz to 0.01 Hz.

Transmission electron microscopy (TEM) images of Fe/Fe$_3$O$_4$/N-carbon are shown in Fig. 6. Particles less than 100 nm are dispersed on the RHC matrix (Fig. 6a). These nanoparticles may be either Fe$_3$O$_4$ or Fe nanoparticles in the frame work formed during calcination process, which have been confirmed by XRD. The average particle size is estimated to be around 47 nm (Fig. 6b), which is consistent with that of the XRD analysis. The crystal structure of Fe/Fe$_3$O$_4$ nanoparticles is revealed by the HRTEM images in Fig. 4b. The lattice spacings of 2.53 Å and 2.03 Å are ascribed to the (311) plane of Fe$_3$O$_4$ and the (110) plane of Fe, respectively. The presence of weak and large rings in the SAED pattern (Fig. 6c) for Fe/Fe$_3$O$_4$/N-carbon is evidence for the loss of sample crystallinity, in agreement with the XRD data. A randomly selected nanoparticle magnified in Fig. 6d indicated that it is wrapped by thin graphene-like layers of 5-10 nm in thickness. Further investigation of this graphene-like layers found that the inter planar distance is about 0.34 nm (Fig. 6e), consisting of 5-20 graphene-like layers. The correspondingly SAED pattern also showed in Fig. 6f. The graphene-like layers were likely formed from the pyrrole vapour or other carbonaceous gasses resulted from the decomposition of rice husks with the aid of catalytic iron oxide or iron during the calcination at 800 ºC. These well graphitized interconnect frame networks would provide a good electronic conductivity to the composite.

The cyclic voltammogram(CV) curves of Fe/Fe$_3$O$_4$/N-carbon composite for the first two and fifth cycles in the voltage range from 3.0 to 0.01 V at a scan rate of 0.01 mV s$^{-1}$ are shown in Fig. 7a. Two reduction peaks are observed in the first cathodic scan of both Fe/Fe$_3$O$_4$/N-carbon. The peak at around 0.44V, which are absent in the second cycle, is ascribed to the possible irreversible formation of solid electrolyte interface (SEI) film. The other at around 1.30 V indicates an irreversible reduction of Fe$^{3+}$ to Fe$^{2+}$. The anodic curves also have two peaks which are centered at about 1.59V and 0.98V, corresponding to the reversible oxidation of Fe$^{2+}$ to Fe$^{3+}$ or Fe$^{2+}$, respectively. The peak intensity and integral areas of the fifth cycle are close to that of the second one. These results indicate that the electrochemical reversibility of Fe/Fe$_3$O$_4$/N-carbon are gradually built after the initial cycle.

The discharge/charge profiles for the first, the 2nd and the 30th cycles at 50 mA g$^{-1}$ are given in Fig. S3†. Fe/Fe$_3$O$_4$/N-carbon shows a first-cycle insertion capacity of 748 mAh g$^{-1}$ and a de-insertion capacity of 633 mAh g$^{-1}$, corresponding to a
Columbic efficiency of 85%. The second discharge and charge capacities are 594 and 545 mAh g⁻¹, respectively, with the Columbic efficiency over 91%. Fe/Fe₃O₄/carbon shows a first-cycle insertion capacity of 647 mAh g⁻¹ and a de-insertion capacity of 450 mAh g⁻¹, corresponding to a Columbic efficiency of 70%. The second discharge and charge capacities are 517 and 440 mAh g⁻¹, respectively, with the Columbic efficiency over 85%. The incorporation of porous carbon with N-doped graphene-like structure significantly improve the electrochemical performance of iron oxides.

The cycling performance of Fe/Fe₃O₄/N-carbon, Fe/Fe₃O₄/carbon and RHC as anode materials for lithium ion batteries at the current density of 200 mA g⁻¹ was evaluated and the results are shown in Fig. 7b. The reversible capacity of Fe/Fe₃O₄/N-carbon is ~703 mAh g⁻¹ in the first cycle and then stabilizes at ~510 mAh g⁻¹ after 10 cycles. Interestingly, the capacity gradually increased to ~610 mAh g⁻¹ after 100 cycles. The reversible capacity of Fe/Fe₃O₄/carbon was ~647 mAh g⁻¹ in the first cycle and then stabilized at ~413 mAh g⁻¹ after 10 cycles and then gradually increased to ~460 mAh g⁻¹. This special phenomenon, of the increase in capacity with cycling, can be attributed to the activating process of the porous anode as reported in Huang’s work. However, the porous RHC matrix did not show similar phenomenon when evaluated in the same condition. Thus the increase of the capacity with cycling must be the consequence of activating process of the N doping and iron oxide nanoparticles. The low reversible capacity (~260 mAh g⁻¹) of RHC matrix under the same condition also confirm the validity of N doping and activated nanoparticle association by facile treatment. Among these two factors, the N-doping is the main because the capacity increase is ~100 mAh g⁻¹ for Fe/Fe₃O₄/N-carbon and ~47 mAh g⁻¹ for Fe/Fe₃O₄/carbon respectively.

Fig. 7c presents the rate performance of Fe/Fe₃O₄/N-carbon at current densities of 200, 500, 1000, 2000 and 10000 mA g⁻¹, and the reversible specific capacity of 507, 301, 293, 233 and 116 mAh g⁻¹ are obtained respectively. Even at a higher current density of 10000 mA g⁻¹, the reversible specific capacity is still above 116 mAh g⁻¹. The reversibility is demonstrated by the fact that a high capacity 491 mAh g⁻¹ is reached again once the rate is lowered back to 200 mA g⁻¹. However Fe/Fe₃O₄/carbon has the reversible capacity of 405 mAh g⁻¹ at the current density of 200 mA g⁻¹, which is about 20% lower than that of the N-doped counterpart. A reversible capacity of 264mAh g⁻¹ for RHC has been obtained upon varying the discharge rate from 200 to 10000 and then back to 200 mA g⁻¹. Therefore, not only the rate performance of Fe/Fe₃O₄/N-carbon is much better than that of either Fe/Fe₃O₄/carbon or RHC, but a higher capacity can be reached at a much higher rate.

The electrochemical impedance spectra (EIS) studies of Fe/Fe₃O₄/N-carbon, Fe/Fe₃O₄/carbon and RHC after 5 cycles and Fe/Fe₃O₄/N-carbon before cycles (Fig. 7d) were performed on a Chenhua CHI 660 electrochemical workstation. The Nyquist plots of Fe/Fe₃O₄/N-carbon, Fe/Fe₃O₄/carbon and RHC after 5 cycles and Fe/Fe₃O₄/N-carbon before cycles show a semicircle in the high frequency range and a sloping straight line in the low frequency range. The equivalent circuit of the electrodes is shown in Fig. S4† where R, CPE, Rct, W are denoted as solution resistance, double layer capacitance, charge-transfer resistance and Warburg impedance, respectively. The charge-transfer resistance (Rct) of the Fe/Fe₃O₄/N-carbon is calculated to be approximately 81.1 Ω after 5 cycles from 117.8 Ω, much lower than that of the Fe/Fe₃O₄/carbon and RHC electrode electrode (approximately 162.3 and 228.6Ω). The decreased resistance of the Fe/Fe₃O₄/N-carbon electrode is attributed to in situ graphene-like layers and Fe nanoparticles with excellent electrical conductivity.

The microstructure variation of Fe/Fe₃O₄/N-carbon after 100 discharge-charge cycles were examined using TEM (Fig. S5†). Obviously, no aggregation occurred and the nanoparticles are observed dispersing well after cycling. This structure observation of Fe/Fe₃O₄/N-carbon is well consistent with its cycling performance.

Consequently, the low resistance leads to the significantly enhanced rate capability of the Fe/Fe₃O₄/N-carbon composite. It is known that the depth of lithium ion intercalation and de intercalation in the non-graphitic carbonaceous materials strongly depends on the anode composition and structure such as crystalline phase, hydrogen content, microstructure and micromorphology. As demonstrated by Zhou et al. that large and ordered pore arrays are very beneficial to the intercalation of lithium, which is known as a slow bulk-phase reaction. The hierarchical structure of our Fe/Fe₃O₄/N-carbon composite is readily accessed by the electrolyte solution; that is, Li⁺ ions can freely move into large pores and intercalate into the thin pore walls and the N-loading location. Therefore, the high reversibility of Li storage is probably due to the following reasons. (i) The grain size of the activated nanoparticles is less than 50 nm, which limits the anode volume change and reduces the path for Li⁺ transportation. (ii) Porous carbon prevents the aggregation of activated nanoparticles. (iii) Graphene-like networks, N-doping and the generation of Fe nanoparticles increase electronic conductivity. (iv) N-doping increases the potential Li⁺ insertion locations during discharge and charge. (v) The hierarchical structure with a high surface area provides a large electrode/electrolyte contact area and a favorable pore texture for electrolyte impregnation, thus improving the anode performance. Our results clearly demonstrate that Fe/Fe₃O₄/N-carbon prepared by divertive fabrication is a promising candidate for anode materials of high reversible capacity, good cycle performance and high rate discharge/charge capability in used LIBs.

4. Conclusions
Nitrogen-doped porous carbon containing activated nanoparticles and graphene-like layers was synthesized by a simple impregnation then polymerization and carbonation method. The resultant composite Fe/Fe₃O₄/N-carbon has a hierarchical porous structure of rice husk and contains N-doped graphene-like networks and Fe&Fe₃O₄ nanoparticles and has a
high specific surface area of 1151 m² g⁻¹. When used as anode in LIB, it showed a high discharge capacity of 610 mA h g⁻¹ at 200 mA g⁻¹ after 100 cycles and a high rate performance. Considering the abundant hierarchical structures in nature, the strategy here reported is expected to be extended for design and fabrication of other anode materials with unique structures and composition.

A Novel Fe/Fe₃O₄/N-carbon composite with hierarchical porous structure and in situ formed N-doped graphene-like layers for high-performance lithium ion batteries

Yao Li, Qing Meng, Shen-min Zhu, Zeng-hui Sun, Hao Yang, Zhi-xin Chen, Cheng-ling Zhu, Zai-ping Guo, and Di Zhang

A Fe/Fe₃O₄/N-carbon composite consisting of porous carbon matrix containing a highly conductive N-doped graphene-like network and Fe/Fe₃O₄ nanoparticles was prepared. The porous carbon has hierarchical structure which inherits from rice husk and N-doped graphene-like network formed in situ. When used as an anode material for lithium batteries, the composite delivered a reversible capacity of approximately 610 mAh g⁻¹ at a current density of 200 mA g⁻¹ even after 100 cycles, due to the synergism between the unique hierarchical porous structures, highly electric conductive N-doped graphene-like networks and nanosized particles of Fe/Fe₃O₄. This work provides a simple approach to prepare N-doped porous carbon activated nanoparticle composite which could be used to improve the electrochemical performance of lithium ion batteries.
