Oscillating sharp edges have been employed to achieve rapid and homogeneous mixing in microchannels using acoustic streaming. Here we use a perturbation approach to study the flow around oscillating sharp edges in a microchannel. This work extends prior experimental studies to numerically characterize the effect of various parameters on the acoustically induced flow. Our numerical results match well with the experimental results. We investigated multiple device parameters such as the tip angle, oscillation amplitude, and channel dimensions. Our results indicate that, due to the inherent nonlinearity of acoustic streaming, the channel dimensions could significantly impact the flow patterns and device performance.

1 Introduction

Microfluidic devices can be effective in many applications including biomedical diagnostics, drug delivery, chemical synthesis, and enzyme reactions. An important requirement for these systems is the ability to rapidly and efficiently mix small amounts of samples at microscales. Various techniques have been utilized to enable rapid mixing in microfluidic devices including chaotic advection, hydrodynamic focusing, electrokinetically driven mixing, 3D combinatorial bubble-based mixing, and thermally-induced mixing, as well as optically-induced mixing. Recently, acoustic-based mixers have generated significant interest because of their non-invasive nature. These mixers utilize acoustic waves to perturb the laminar flow pattern in microchannels to achieve rapid and homogeneous mixing. In particular, acoustically driven, oscillating bubbles have been used to achieve fast and homogeneous mixing by generating acoustically-induced microvortices. Bubble-based acoustic mixers have been utilized in enzyme reaction characterization, DNA hybridization enhancement, and chemical gradient generation, as well as optofluidic modulators. However, bubble-based acoustic mixers have also proven to be challenging due to bubble instability, heat generation, and hard-to-control bubble-trapping processes. To overcome these difficulties, we recently reported a sharp-edge-based micro-mixer where the flow field is perturbed using microvortices generated by an acoustically oscillating sharp edge. The performance of the sharp-edge based micro-mixer was found to be very close to that of the bubble-based micro-mixer with the added advantage of convenient and stable operation over bubble-based micro-mixers. However, to realize the full potential of these devices and explore further applications, a deeper understanding of the flow field around oscillating sharp edges is required.

Steady streaming around obstacles in an oscillating incompressible fluid has been studied extensively. Due to the dissipative nature of the fluid, the response to a time-harmonic forcing is generally not harmonic. The fluid’s response to a harmonic forcing can be viewed as a combination of a time harmonic response, generally referred to as acoustic response, and a remainder, referred to as acoustic streaming. Time averaging of the Navier-Stokes equations yields a term analogous to the Reynolds stress which causes a “slow” steady streaming around obstacles in the flow field. This can also be interpreted by saying that the nonlinear hydrodynamic coupling results in a partial transmission of the acoustic wave energy to the fluid as steady momentum resulting in acoustic streaming. Since the latter is a byproduct of the acoustic attenuation due to viscous dissipation, it provides a unique way to utilize the dominant viscous nature of microfluidic flows. It is important to remark that there are two main dissipation mechanisms: (1) wave attenuation in the bulk fluid, and (2) dissipation in the boundary, in which the streaming in the boundary layer drives streaming in the bulk. Both mechanisms owe their origin to the action of Reynolds stress. It is the acoustic energy flux dissipation that induces momentum flux gradients, and these, in turn, drive acoustic streaming. While in the first case dissipation occurs in the bulk fluid, in the second case most of the dissipation occurs within boundary layers at the solid sur-
faces. The dominance of one mechanism over the other is dependent on the size of the device. For devices where the microchannel is very small compared to the wavelength and the attenuation length, like the one used in this article, the streaming will be boundary layer driven.

While bubble-based mixers have been extensively studied both analytically and numerically, 33,37,52,53 the knowledge of flow fields around oscillating sharp edges is limited. Lieu et al. 49 have studied the flow around obstacles in an oscillating incompressible flow field. However, Lieu et al. 49 do not discuss possible singularities induced in the flow by the geometry of the obstacles. In addition, their analysis is not directly applicable to our system, which is characterized by acoustic wave propagation, the latter requiring an explicit modeling of the fluid compressibility. Although steady streaming has been widely studied for cases where the fluid can be treated as infinite, little attention has been given to this phenomenon in confined flows. 49 The basic hydrodynamic traits of low Reynolds number flows in microfluidic channels are dictated by the motion of the walls. This, coupled with the inherent nonlinearity of the acoustic streaming phenomena, implies that the geometrical dimensions of the microchannel and the boundary conditions significantly impact the flow field around the oscillating sharp edge inside a microchannel. These considerations justify a numerical approach to study the flows in question in which the geometry of the walls can be accurately represented.

In this work, we numerically investigate the acoustic streaming generated in a fluid by oscillating sharp edges inside a microchannel. We build on our previous experimental studies and aim at characterizing the effect of various parameters on the micro-eddies around the sharp edges. We model the fluid as compressible and linear viscous so that the fluid’s equations of motion are the compressible Navier-Stokes equations. These are intrinsically nonlinear and characterized by different behaviors over wide ranges of time and length scales. The flow on the large length- and time-scales arises from the acoustic excitation at much smaller time and length scales. 28 Consequently, a direct solution of the compressible Navier-Stokes equation remains computationally challenging even with modern computational tools. To overcome this difficulty, we employ Nyborg’s perturbation approach 51 complemented by periodic boundary conditions. To capture the singularity in the flow field, we refine the mesh near the tip of the sharp edge using an adaptive mesh refinement strategy. Our approach is general in the sense that we do not make a priori assumptions about specific flow regimes in selected regions of the computational domain. After identifying boundary conditions that lead to predictions matching experimental observations, we numerically investigate the effects of various parameters like tip angle, displacement amplitude, and channel dimensions on the streaming velocity and particle mean trajectories. The numerical methods and results presented in this article will be useful in optimizing the performance of acoustofluidic devices and providing design guidelines.

2 Micro-acousto-fluidic channel with sharp edges

Figure 1(a) provides a schematic of the oscillating sharp-edge-based acoustofluidic micromixer. A single-layer polydimethylsiloxane (PDMS) channel with eight sharp-edges on its sidewall (four on each side) was fabricated using standard soft lithography and bonded onto a glass slide. A piezoelectric transducer (model no. 273-073, RadioShack®) was then attached adjacent to the PDMS channel. Upon the actuation of the piezoelectric transducer, the sharp-edges were acoustically oscillated with a frequency of 4.75kHz. These oscillations generate a pair of counter-rotating vortices (double-ring recirculating flows) in the fluid around the tip of each sharp-edge, as shown in Fig. 1(b). Typical channel dimensions are indicated in Fig. 1(c). To visualize and characterize the streaming flow inside the channel, a solution containing 1.9 µm diameter dragon green fluorescent beads (Bangs Laboratories, Inc.™) was introduced into the channel. The typical bead trajectories observed in experiments are shown in Fig. 2.
Fig. 2 Experimentally observed trajectories of 1.9 μm diameter fluorescent polystyrene beads in our acoustically oscillated micro-mixer with sharp edges. The geometry of the micro-channel is described in Fig. 1(c) except for the fact that here, the tips of the sharp edges are 200 μm from the wall instead of 250 μm. The driven oscillation is harmonic with a frequency equal to 4.75 kHz.

3 Modeling

We denote vector quantities by boldface type and scalars by a normal-weight font.

The mass and momentum balance laws governing the motion of a linear viscous compressible fluid are

\[ \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0 \]  
(1)

and

\[ \rho \frac{\partial \mathbf{v}}{\partial t} + \rho (\mathbf{v} \cdot \nabla) \mathbf{v} = -\nabla p + \mu \nabla^2 \mathbf{v} + (\mu_b + \frac{1}{2} \mu) \nabla (\nabla \cdot \mathbf{v}), \]  
(2)

where \( \rho \) is the mass density, \( \mathbf{v} \) is the fluid velocity, \( p \) is the fluid pressure, \( \mu \) and \( \mu_b \) are the shear and bulk dynamic viscosities, respectively. The fields \( \rho \), \( p \), and \( \mathbf{v} \) are understood to be in Eulerian form, \( t \), i.e., functions of time \( t \) and of the spatial position \( \mathbf{x} \) within a chosen control volume. Equations (1) and (2), with appropriate boundary conditions and a constitutive relation linking the pressure to the fluid density, allow one to predict the motion of the fluid. We assume the relation between \( p \) and \( \rho \) to be linear:

\[ p = c_0^2 \rho, \]  
(3)

where \( c_0 \) is the speed of sound in the fluid at rest. Direct simulation of this non-linear system of equations poses significant numerical challenges owing to the widely separated length (characteristic wave lengths vs. the characteristic geometrical dimensions of the microfluidic channels) and time scales (characteristic oscillation periods vs. characteristic times dictated by the streaming speed).\(^{56} \) Because of viscous dissipation, the response of the fluid to a harmonic forcing is, in general, not harmonic. The fluid response is generally thought to be comprised of two components: (i) a periodic component with period equal to the forcing period, and (ii) a remainder that can be viewed as being steady. It is this second component which is generally referred to as the streaming motion.\(^{48} \)

We employ Nyborg’s perturbation technique\(^{51} \) in which fluid velocity, density, and pressure are assumed to have the following form:

\[ \mathbf{v} = \mathbf{v}_0 + \varepsilon \mathbf{v}_1 + \varepsilon^2 \mathbf{v}_2 + O(\varepsilon^3) + \cdots, \]  
(4a)

\[ p = p_0 + \varepsilon p_1 + \varepsilon^2 p_2 + O(\varepsilon^3) + \cdots, \]  
(4b)

\[ \rho = \rho_0 + \varepsilon \rho_1 + \varepsilon^2 \rho_2 + O(\varepsilon^3) + \cdots, \]  
(4c)

where \( \varepsilon \) is a non-dimensional smallness parameter. Following Köster,\(^{57} \) we define \( \varepsilon \) as the ratio between the amplitude of the displacement of the boundary in contact with the piezoelectrically driven substrate (i.e., the amplitude of the boundary excitation) and a characteristic length. We take the 0-th order velocity field \( \mathbf{v}_0 \) to be equal to zero thus assuming the absence of an underlying net flow along the micro-channel. Letting

\[ \mathbf{v}_1 = \varepsilon \mathbf{v}_1, \quad p_1 = \varepsilon p_1, \quad \rho_1 = \varepsilon \rho_1, \]  
\[ \mathbf{v}_2 = \varepsilon^2 \mathbf{v}_2, \quad p_2 = \varepsilon^2 p_2, \quad \rho_2 = \varepsilon^2 \rho_2, \]  
(5)

substituting Eqs. (4) into Eqs. (1) and (2), and setting the sum of all the terms of order one in \( \varepsilon \) to zero, the following problem, referred to as the first-order problem, is obtained:

\[ \frac{\partial \rho_1}{\partial t} + \rho_0 (\nabla \cdot \mathbf{v}_1) = 0, \]  
(6)

\[ \rho_0 \frac{\partial \mathbf{v}_1}{\partial t} = -\nabla p_1 + \mu \nabla^2 \mathbf{v}_1 + (\mu_b + \frac{1}{2} \mu) \nabla (\nabla \cdot \mathbf{v}_1). \]  
(7)

Repeating the above procedure for the terms of order two in \( \varepsilon \), and averaging the resulting equations over a period of oscillation, the following set of equations, referred to as the second-order problem, is obtained:

\[ \left\langle \frac{\partial \rho_2}{\partial t} \right\rangle + \rho_0 \left\langle \nabla \cdot \mathbf{v}_2 \right\rangle = -\left\langle \nabla \cdot \mathbf{v}_1 \right\rangle, \]  
(8)

\[ \rho_0 \left\langle \frac{\partial \mathbf{v}_2}{\partial t} \right\rangle + \left\langle \left( p_1 - \frac{\partial \rho_1}{\partial t} \right) \frac{\partial \mathbf{v}_1}{\partial t} \right\rangle + \rho_0 \left\langle \nabla \cdot \mathbf{v}_1 \right\rangle \cdot \nabla \cdot \mathbf{v}_1 \]  
\[ = -\left\langle \nabla \cdot \mathbf{v}_2 \right\rangle + \mu \left\langle \nabla^2 \mathbf{v}_2 \right\rangle + (\mu_b + \frac{1}{2} \mu) \nabla \cdot \mathbf{v}_2, \]  
(9)

where \( \langle \cdot \rangle \) denotes the time average of the quantity \( \chi \) over a full oscillation time period. As pointed out by Stuart,\(^{45,58} \) inertia terms in Eq. (9) can be significant and must be retained in the formulation. Also, to fully account for viscous attenuation of the acoustic wave, both within and without the boundary layer, the last term in Eq. (9) associated with the bulk viscosity must also be retained. The above sets of equations need to be complemented by appropriate boundary conditions. Referring to
on the transducer to corresponding loading conditions on the channel. Rather, we formulate simple boundary conditions based on observations from our prior experimental work.\textsuperscript{41} Referring to Figs. 1(a) and 3, we observe that the diameter of the transducer is much larger than the transverse width of the channel (\( \approx 600 \mu m \)) so that the channel can be assumed to be subject to a plane wave parallel to the \( x \) direction and traveling in the \( y \) direction. It must be noted that this assumption cannot be used if the wavelength of the acoustic wave is comparable to the channel dimensions. In that case, one needs to consider the radial nature of the acoustic wave. In the device used in this article, the wavelength of the acoustic wave (\( \approx 30 \) cm) is much larger than the channel width (\( \approx 600 \mu m \)). Hence, we assume that the boundary portions \( \Gamma_t \) and \( \Gamma_b \) (the solid lines in Fig. 3(b), including the sharp edge structures) are subject to a displacement field \( \mathbf{w}(\mathbf{x}, t) \) of the following form

\[
\mathbf{w}(\mathbf{x}_t, t) = \mathbf{w}_t^c \cos(2\pi ft) + \mathbf{w}_t^s \sin(2\pi ft), \\
\mathbf{w}(\mathbf{x}_b, t) = \mathbf{w}_b^c \cos(2\pi ft) + \mathbf{w}_b^s \sin(2\pi ft),
\]

where \( \mathbf{w}_t^c, \mathbf{w}_t^s, \) and \( \mathbf{w}_b^c \) are vector-valued constants, and where \( f \) is the transducer oscillation frequency in hertz. Consistently with the asymptotic expansion in Eqs. (4), the boundary conditions on \( \Gamma_t \) and \( \Gamma_b \) for the first-order problem are\textsuperscript{57,59} \( \mathbf{v}_1(\mathbf{x}_t, b, t) = \partial \mathbf{w}(\mathbf{x}_t, b, t) / \partial t, \) which gives

\[
\mathbf{v}_1(\mathbf{x}_t, b, t) = -2\pi f [\mathbf{w}_t^c \sin(2\pi ft) - \mathbf{w}_t^s \cos(2\pi ft)],
\]

where the subscripts and superscripts \( t \) and \( b \) stand for ‘on \( \Gamma_t \)’ and ‘on \( \Gamma_b \)’, respectively. For the second-order problem we have\textsuperscript{57,59}

\[
\mathbf{v}_2(\mathbf{x}_b, t) = -\left( (\mathbf{w}(\mathbf{x}_t, t) \cdot \nabla) \mathbf{v}_1(\mathbf{x}_t, b, t) \right).
\]

As already mentioned, and referring to Figs. 2 and 3, experimental results are characterized by distinctive symmetries. Hence, for both the first- and second-order problems, we enforce periodic boundary conditions along the \( x \) direction, that is on \( \Gamma_t \) and \( \Gamma_r \). Specifically, for all pairs of homologous points \( \mathbf{x}_t \) and \( \mathbf{x}_r \) on \( \Gamma_t \) and \( \Gamma_r \), respectively, we demand that

\[
\mathbf{v}_1(\mathbf{x}_t, t) = \mathbf{v}_1(\mathbf{x}_r, t) \quad \text{and} \quad \mathbf{v}_2(\mathbf{x}_t, t) = \mathbf{v}_2(\mathbf{x}_r, t).
\]

As far as the \( y \) direction is concerned, we observe that the wave length of the forced oscillations in the substrate is much larger than the channel’s width. Hence, we subject \( \Gamma_t \) and \( \Gamma_b \) to identical (uniform) boundary conditions as though the channel were rigidly and harmonically displaced in the vertical direction:

\[
\mathbf{w}(\mathbf{x}_b, t) = \mathbf{w}(\mathbf{x}_t, t).
\]

For comparison purposes, and noticing that the experiments suggest the presence of an anti-symmetric pattern relative to
the vertical mid-line of the solution domain, we have also con-

considered the following boundary condition:

\[ w(x_0, t) = -w(x, t). \]  \hspace{1cm} (15)

While the boundary condition in Eq. (12) is common in
streaming problems, its use for a sharp-edge device is prob-
lematic. Our domain has re-entrant corners at the sharp edges
so that the solution of the first-order problem, while bounded,
has singular velocity gradients at the sharp edges. Therefore,
Eq. (12) implies that, at the sharp edges, not only are the vel-

ocity gradients of the second-order solution singular, but the
very velocity field is also singular. This feature of the solution,
which is intrinsic to a geometry with re-entrant corners, seems
to have been neglected in other studies. In order to remove
the singularity in the second-order velocity, one would have to
set the displacement at the sharp edge to zero and, possibly,
control its growth away from the edge. However, this con-

straint is difficult to justify on practical and physical grounds
due to the very design of the microfluidic channel of interest.

Hence, and with the expectation to accurately capture the so-
lution only outside the Stokes boundary layer, we proceeded
to determine numerical solutions without taking any special
precautions other than the use of a reasonable adaptive mesh
refinement scheme as described later.

3.2 Mean trajectories

Figure 2 shows the mean trajectories of polystyrene spherical
beads placed in the fluid for streaming flow visualization pur-
poses. As this is the primary piece of experimental evidence
at our disposal, we wish to establish whether or not our calcu-
lations are able to reproduce a flow pattern similar to that in
Fig. 2. The beads used in Fig. 2 are the same as those used
by Bruus and co-workers \(^{60-64}\) who have carefully studied the
scattering problem that arises by the release of these beads
within a streaming flow. We believe the results by Bruus and
coworkers to be rigorous and we have implemented in our
software the tracking strategy they proposed. \(^{60-64}\) This strategy
is predicated on the determination of the radiation force acting
on a bead of radius \(a\), mass density \(\rho_p\), and compressibility \(\kappa_p\)
under the influence of a standing wave in the flow. The bead
is modeled as a wave scatterer, and the radiation force is then
found to be

\[ F_{\text{rad}} = -\frac{4\pi a^3}{3} \left[ \left(f_1 \kappa_0 \nabla \langle p^2 \rangle \right) - \frac{3}{4} \rho_0 \text{Re}(f_2) \nabla \langle v_1 \cdot v_1 \rangle \right], \]  \hspace{1cm} (16)

where \(\kappa_0 = 1/(\rho_0 c_0^2)\) is the compressibility of the fluid, \(\text{Re}(f_2)\)
is the real part of \(f_2\), and where

\[ f_1 = 1 - \frac{\kappa_p}{\kappa_0} \quad \text{and} \quad f_2 = \frac{2(1 - \gamma)(\rho_p - \rho_0)}{2\rho_p + \rho_0(1 - 3\gamma)}, \]  \hspace{1cm} (17)

with

\[ \gamma = -\frac{3}{2}[1 + i(1 + \delta)]\delta, \quad \delta = \frac{\delta}{\rho}, \quad \delta = \sqrt{\frac{\mu}{\pi f \rho_0}}, \]  \hspace{1cm} (18)

and the symbol ‘\(i\)’ denotes the imaginary unit. In addition to
the radiation force, a bead is assumed to be subject to a drag
force proportional to \(v_{\text{bead}} - \langle v_2 \rangle\), which is the velocity of
the bead relative to the streaming velocity. When wall effects
are negligible, the drag force is estimated via the simple formula

\[ F_{\text{drag}} = 6\pi\mu a \langle v_2 \rangle - v_{\text{bead}} \]  \hspace{1cm} (19)

For steady flows, we can identify the bead trajectories with the
streamlines of the velocity field \(v_{\text{bead}}\) in Eq. (20).

For an “ideal tracer,” a bead with the same density and
compressibility as the surrounding fluid, \(F_{\text{rad}} = 0\) and the bead’s
velocity coincides with the streaming velocity. However, it is
well known that the trajectories of the streaming velocity
field (or its streamlines in steady problems) are not fully rep-

resentative of the mean trajectories of the fluid’s particles as
the latter are subject to a drift effect known as Stokes drift. \(^{65}\)
The theory around the Stokes drift is developed without refer-
ence to the motion of a bead in the fluid and therefore it can be
viewed as a theory for the identification of mean trajectories
of fluid particles. We adopt the theory of Lagrangian mean
flow described by Bühler, \(^{66}\) and employed by Vanneste
and Bühler, \(^{67}\) in which mean particle paths are the trajectories
of a velocity field referred to as the Lagrangian velocity, denoted
by \(v^L\), and given by

\[ v^L = \langle v_2 \rangle + \left(\langle\xi_1 \cdot \nabla\rangle v_1\right), \]  \hspace{1cm} (21)

where the field \(\xi_1(x, t)\) is the first-order approximation of the
lift field \(\xi(x, t)\). The latter is defined such that \(x + \xi\) represents
the true position at time \(t\) of a particle with mean position at \(x\)
(also at time \(t\)). By asymptotic expansion, \(\xi_1\) is such that

\[ \frac{\partial \xi_1}{\partial t} = v_1. \]  \hspace{1cm} (22)

Equation (22) implies that, once the first-order problem
velocity solution of the form \(v_1 = v_1^t(x) \cos(2\pi ft) + v_1^L(x) \sin(2\pi ft)\) is computed, \(\xi_1\) can be calculated during
post-processing via an elementary time integration. For a
steady problem, the trajectories of the fluid particles are then
the streamlines of \(v^L\).
Differently from \( \mathbf{v}^{\text{bead}} \), \( \mathbf{v}^{\text{L}} \) is an intrinsic property of the combination of the first- and second-order solutions of the acoustofluidic problem. That is, \( \mathbf{v}^{\text{L}} \) arises from kinematic arguments alone without reference to the balance of linear momentum or the balance of mass. As such, the Lagrangian velocity field does not coincide with either \( \mathbf{v}^{\text{bead}} \) or the mean velocity of the mass flow.\(^{68,69}\) The latter, denoted by \( \mathbf{v}^{\text{M}} \), is defined such that \( \rho_0 \mathbf{v}^{\text{M}} \) gives the second-order approximation of the linear momentum flow per unit volume:

\[
\mathbf{v}^{\text{M}} = \langle \mathbf{v}_2 \rangle + \frac{1}{\rho_0} \langle \mathbf{p}_1 \mathbf{v}_1 \rangle. \tag{23}
\]

As already alluded to, \( \mathbf{v}^{\text{bead}}, \mathbf{v}^{\text{L}}, \) and \( \mathbf{v}^{\text{M}} \) introduce corresponding notions of mean flow trajectories which can be quite distinct from one another. However, they all carry useful information about the solution.

### 3.3 Numerical solution approach

As is customary in acoustic streaming problems, we seek time-harmonic solution for \( \mathbf{v}_1 \) and \( p_1 \) in the first-order problem, while we seek steady solutions for \( \mathbf{v}_2 \) and \( p_2 \) in the second-order problem. Combining information from these two solutions, it is then possible to estimate the mean trajectory of material particles in the flow.

All the solutions discussed later are for two-dimensional problems. The numerical solution was obtained via an in-house finite element code based on the deal.II finite element library.\(^{68,69}\) For both the first- and second-order problems we used \( Q2-Q1 \) elements for velocity and pressure, respectively, where \( Q1 \) and \( Q2 \) denote quadrilateral elements supporting Lagrange polynomials of order one and two, respectively. Our code was developed using the mathematical framework discussed by Köster\(^57\) who offered a very careful analysis of the numerical properties of the approach. The main fundamental difference between our code and that by Köster is the use of adaptivity. Specifically, to mitigate somewhat the effects of the singularities discussed earlier, we adopted a very traditional adaptive mesh refinement strategy with an error estimator based on the solution’s gradients.\(^70\) Our specific error estimator was based on the gradient of the velocity solution of the first-order problem. The flow patterns we present are those that did not significantly change upon further refinement of the mesh outside the Stokes boundary layer. Clearly, we make no claims on the values of the velocity gradients within this layer near the sharp edges.

### 4 Results and Discussion

#### 4.1 Constitutive Parameters

All of the results presented were obtained using the values in Table 1 for the constitutive and operational parameters in the governing equations. Some of the results pertain to the motion of a dilute concentration of 1.9 \( \mu \text{m} \) diameter fluorescent beads. The frequency employed in simulations was chosen because it is the frequency used in prior experimental work from our group on a sharp-edge acoustic mixer with the same geometry considered herein.\(^41\) As frequency is related to wavelength, our choice of frequency must also be consistent with the assumption discussed in Section 3.1 concerning the channel being subject to a plane wave with wavelength of roughly 30 cm. With this in mind, streaming effects in microacoustofluidic devices are typically more evident at higher frequencies, i.e., in the MHz regime. We have not considered such high frequencies in the present study because we feel that our assumption concerning the wave impinging on the channel would no longer be acceptable. However, for the purpose of comparison, we did carry out a simulation with frequency of 4.75 MHz and presented the corresponding results in the Supplementary Information (Section III, Fig. 3).

#### 4.2 In lieu of convergence tables

As mentioned earlier, the gradients of the first-order velocity and the second-order velocity field are unbounded at the tips of the sharp edges. As such, the second order velocity solution does not converge in a strict sense. Nonetheless, it turns out that the singularity effects are all contained within the Stokes boundary layer and it is therefore still possible to talk about an effective notion of convergence outside this layer. To illustrate this idea, we present in Fig. 4A plots of the magnitude of the second-order velocity \( \mathbf{v}_2 \) as a function of position along a line parallel to the \( y \) axis (cf. Fig. 3) and emanating from the tip of the lower sharp edge as shown in red in the left inset of Fig. 4. The latter shows three curves corresponding to in-
4.3 Effects of boundary conditions on $\Gamma$ and $\Gamma_b$

In Section 3.1, we discussed two possible expressions for the boundary conditions on the $\Gamma$ and $\Gamma_b$ (cf. Fig. 3) portions of the solution’s domain. Figure 5 shows our numerical solution for the velocity $v^{\text{bead}}$ in Eq. (20) of beads in the flow. Referring to Fig. 3, the results in the above figure were obtained for a channel with $L = 300 \mu m$, $H = 600 \mu m$, $\alpha = 15^\circ$, and $h = 200 \mu m$. In both cases, the wall displacement was completely in the $y$ direction with an amplitude of $1 \mu m$. In both cases, we observe that eddies are predicted with streamlines symmetric relative to the (geometric) center of the simulation domain. This features matches the experimentally obtained bead traces in Fig. 2. However, we notice that in the experiments there is no evidence of large eddies at the foot of the sharp edges, as predicted using the anti-periodic boundary conditions in Eq. (15). Furthermore, we observe that the magnitude of $v^{\text{bead}}$ is vastly different in the two cases. In fact, even in some regions outside the Stokes layer, the velocity predicted in Fig. 5(b) can be of the same order of magnitude as the average flow velocity observed in experiments with a net flow through the channel (absent in our simulations). Instead, the magnitudes in Fig. 5(a) are more compatible with experimental results, as are the predicted streamlines. As discussed in Section 3.1, the boundary conditions used in this work are based on heuristic arguments and under the assumption that the channel is rigid, as opposed to being produced by a more sophisticated piezo-electro-elastic calculation. Despite this approximation, the result in Fig. 5(a) is very much in agreement with experimental observations. Therefore, for the remainder of the paper we will use only the boundary conditions in Eq. (14).

4.4 Mean flows and trajectories

Next, we compare the three different types of mean velocities introduced in Section 3.2, along with their corresponding streamlines. Figure 6 shows plots of $v^{\text{bead}}$, $v^{L}$, and $v^{M}$ for the boundary conditions given by Eq. (14). Again, the channel has the following dimensions: $L = 300 \mu m$, $H = 600 \mu m$, $\alpha = 15^\circ$, and $h = 200 \mu m$; also the wall displacement was completely in the $y$ direction with an amplitude of $1 \mu m$. It is important to note that the three plots in Fig. 6 are the out-
come of a single calculation, that is, they are the product of a single set of geometric parameters and boundary conditions. As discussed earlier in the paper, we view $v^{\text{bead}}$ as the velocity of tracing beads in a fluid. The field $v^{\text{bead}}$ is an attempt to capture in an approximate sense the interaction between the beads and the fluid in which they are immersed. Instead, $v^L$, which is the sum of the second-order velocity and the Stokes drift term, is the so-called Lagrangian velocity and it is the vector field whose trajectories are the mean trajectories of the fluid particles. Finally, $v^M$ is the average mass flow. What Fig. 6 is meant to show is that the above notions of mean flow can indeed be quite different and therefore represent very distinct properties of the same underlying solution. The difference between the streamlines of $v^L$ and the experimental bead trajectories is to be expected. In fact, $v^L$ indicates the trajectory of fluid particles in the absence of the beads in the flow, and thus should not be used for comparison with bead trajectories. On the other hand, $v^{\text{bead}}$, resulting from the balance of radiation force and Stokes drag, describes the motion of the beads and is indicative of the bead trajectories observed in the experiments. We have already established that the bead trajectories are in good qualitative agreement with the experiments. Therefore, we can use the other measures of mean flow with the same degree of confidence. It may be noted from Eq. (20) that the difference between $v^{\text{bead}}$ and the second-order velocity depends on a term that is proportional to the square of the radius of the bead. Thus, as the bead size approaches zero, $v^{\text{bead}}$ tends to the second-order velocity and the bead tracking method essentially consists in studying the mean trajectory of the second-order velocity solution. As the velocity field $v^L$ is an intrinsic property of the flow without any beads in it, we feel that it is a more appropriate descriptor of mean fluid particle trajectories and, as such, a more meaningful descriptor of the mixing properties of the sharp-edge device. Hence, in the remainder of the paper, we will base most of our discussion on plots of $v^L$. Before proceeding further, we observe that the streamlines of $v^L$ do not show eddies for the geometry and boundary conditions used to generate Fig. 6. This is because, for the stated simulation conditions, the Stokes drift effectively cancels the streaming velocity $v_2$. As will be shown later, for other simulation conditions, the Lagrangian velocity will show the existence of eddies in the mean flow.

### 4.5 Effect of displacement amplitude

Next, we study the effect of displacement amplitude prescribed on $\Gamma_t$ and $\Gamma_b$ on the magnitude of the resulting streaming velocity ($v_2$). We simulated the acoustic streaming for different values of the input displacement amplitude and the same geometric parameters used thus far. With this in mind, Fig. 7 shows the plot of the magnitude of the second-order (streaming) velocity measured at a point lying on a line emanating from the tip of a sharp edge parallel to the $y$ direction (cf. Fig. 3).
Plots particle trajectories for three different cases with fixed value of $h = 200 \mu m$ and values of $H = 600 \mu m$, $750 \mu m$, and $900 \mu m$ (cf. Fig 3). The colormap describes the values of the magnitude of the Lagrangian velocity $v^L$, whereas the lines identify the streamlines of $v^L$.}

With this section, we turn to an assessment of the effectiveness of sharp edges in acoustofluidic mixing. Mixing characterization is an inherently complex subject because mixing is a time dependent process. The assessment offered in this paper is limited to the theoretical modeling employed: the equations presented earlier are for a single flow. Therefore, our conclusions are strictly applicable only to perfectly miscible fluids of same density and constitutive properties. As important is the fact that we focus on the analysis of steady state acoustic streaming and therefore we do not consider the time evolution of the fluid. This is not to say that our predictions are inadequate. In fact, analyzing the structure of steady state mean particle trajectories is analogous to analyzing a dynamical system’s response in phase-space to determine the possible evolution of the system as a function of initial conditions, where the latter, in the present context, are the initial positions of fluid particles in the channel. Therefore, given fluid particles initially distributed as shown in Fig. 1(a) near the fluid inlets, we can tell whether or not particles are forced by the device to travel away from their initial position. While we do not solve a time dependent system, we do solve for the streaming velocity. This indicator will allow us to assess whether a particular configuration will achieve mixing more rapidly than another. The mean trajectories we study are the streamlines of the Lagrangian velocity field $v^L$.

Fig. 8 Plots particle trajectories for three different cases with fixed value of $h = 200 \mu m$ and values of $H = 600 \mu m$, $750 \mu m$, and $900 \mu m$ (cf. Fig 3).
region of the domain to be “trapped” (at least temporarily) in a completely different region of the channel. From the viewpoint of mixing with an underlying input flow, the fact that the streaming flow solution displays a very distinct central symmetry indicates that better mixing conditions are achieved by ensuring that the inlet flow be not centered within the channel. Finally, we observe that, as $H$ increases, the fraction of the solution domain experiencing mid-range velocity magnitudes appears to increase.

### 4.7 Effect of the channel dimension $L$

Referring to Fig. 3, $L$ is the distance separating sharp edges on opposite sides of the channel walls. Fig. 9 shows the Lagrange velocity streamlines and magnitudes for three different values of the parameter $L$ equal to 200 µm, 300 µm, and 400 µm. The values of $h$ and $H$ were 200 µm and 600 µm, respectively. The tip angle was set to 15°. These results indicate that increasing the distance between opposing sharp edges does not favor the presence of eddies near the tips. However, the streamlines in Fig. 9(a) seem to indicate the presence of possible stagnation points at the feet of the sharp edges, clearly a feature that would be undesirable. As far as the magnitude of the velocity is concerned, the figures do not indicate sufficiently strong trends in this regard.

### 4.8 Effect of tip angle

Normally, the mixing of fluids occurs as these fluids move along the channel. That is, when there is a net flow, governed by the conditions at the inlets, it interacts with the streaming flow. Provided that we did not consider this interaction, the ability of the device to force particles along the trajectories illustrated thus far depends on the strength of the streaming flow in relation to the background net motion along the channel. For this reason, it is important to determine which, if any, is the design feature that most decisively contributes to the magnitude of the streaming flow. We believe this feature to be the angle $\alpha$ (cf. Fig. 3) at the tip of the sharp edge. It is because $\alpha$ is acute that the second-order solution is singular. It is therefore important to understand how $\alpha$ affects the strength of the streaming flow. Normally, one would have to characterize the type of singularity induced by the tip angle and make inferences on the overall strength of the streaming flow. Unfortunately, no analytical results are available on the analysis of the strength of the singularity at re-entrant corners for asymptotic expansions of the compressible Navier-Stokes equations as employed here. However, in the equations for

**Fig. 9** Plots particle trajectories for three different cases with fixed values of $h = 200 \mu m$ and $H = 600 \mu m$, and different values of (a) $L = 200 \mu m$, (b) $300 \mu m$, and (c) $400 \mu m$ (cf. Fig 3). The colormap describes the values of the magnitude of the Lagrangian velocity $v^L$, whereas the lines identify the streamlines of $v^L$.

![Fig. 10](image-url)

**Fig. 10** Plot of $\|v_2\|$ values at a fixed point ahead of a sharp edge vs. tip angle $\alpha$ (cf. Fig. 3). The dimensions of the channel are $h = 200 \mu m$, $H = 600 \mu m$ and $L = 300 \mu m$. Open circles denote computed data points corresponding to $\alpha = 7.5^\circ$, 15°, 30°, 45°, and 60°. In all cases, $\|v_2\|$ was calculated at the point lying on a line emanating from the tip of a sharp edge parallel to the $y$ direction and a distance away from the tip equal to twice thickness of the Stokes boundary layer.
both the first- and second-order problems, we see the presence of differential operators that are strongly reminiscent of the Navier equations for the linear elastic boundary value problem.

When a re-entrant corner is present in elastic problems, the displacement gradient experiences singularities of the type $1/r^\lambda$, where $r$ is the distance from the tip of the corner and $0 < \lambda < \frac{1}{2}$. For $\alpha \to 0$, $\lambda \to \frac{1}{2}$, which represents the stress/strain behavior found at the tip of a sharp crack. While, the equations used herein are not identical to those of linear elasto-statics, we speculate that the analogy with fracture problems in elasticity might be an appropriate tool to guide us in the interpretation of the results. In order to quantify how the velocity depends on the tip angle, we have measured the magnitude of $v_2$ at a distance equal to $2\delta$ ahead of the tip along a line emanating from the tip and parallel to the $y$, where $\delta$ is the thickness of the Stokes layer. The calculations are reported in Fig. 10. Clearly, the choice of location at which $\|v_2\|$ is measured is arbitrary but it is motivated by the fact that $\|v_2\|$ becomes unbounded as the tip is approached and therefore its measure becomes meaningless. The plot shows that $\|v_2\|$ increases with a decrease of tip angle and that the rate of increase also increases as $\alpha$ becomes smaller. Hence, one immediate conclusion is that the smaller the value of $\alpha$, the stronger the effect of the streaming flow on the overall flow in the device and the better its mixing properties. However, this conclusion needs to be tested by considering the effect of tip angle on particle trajectories. This effect was captured in Fig. 11 for the values of tip angles already mentioned. What is important to notice is that, for $\alpha = 7.5^\circ$ the simulation predicts the appearance of recirculation areas at the feet of the sharp edges that may trap fluid particles permanently. This effect is not entirely surprising since the angle at the sharp edge feet goes to $90^\circ$ as $\alpha$ goes to zero, thus producing stagnation zones in the channel with adverse effect on the device mixing properties. At the same time, we notice that, as the angle becomes smaller, higher values of particle velocity are present over a larger portion of the solution domain. The importance of this observation lies in the fact that higher particle velocities can strongly reduce mixing times and therefore have a very enhancing effect on the mixing properties of the device as a whole.

5 Conclusion

We studied the flow around acoustically actuated oscillating sharp edges inside a microchannel using a perturbation approach. The numerical results were compared with experimental results and a very good agreement was observed between them, especially in view of the strong simplifying assumptions adopted in choosing boundary conditions. We demonstrated that a computational domain with periodic boundary conditions can be used to model the full device, resulting in significant savings in computational costs and time. The predicted flow profiles were found to reflect the inherent nonlinearity of the acoustic streaming phenomena as the various patterns identified are not linear scalings of one another. The flow field was found to be heavily dependent on the geometrical parameters of the device like the tip angle.

![Fig. 11 Plot of $\|v^2\|$ (colormap) and its streamlines for various values of tip angle $\alpha$ (cf. Fig. 3). The dimensions of the channel are $h = 200 \mu m$, $H = 600 \mu m$ and $L = 300 \mu m$. The value of $\alpha$ is (a) 7.5$^\circ$, (b) 15$^\circ$, (c) 30$^\circ$, (d) 45$^\circ$, and (e) 60$^\circ$.

of the sharp edges and the ratio $h/H$ between the distance of the sharp edges from the wall and the overall channel’s width. The streaming velocity was also observed to show a quadratic dependence on the applied input displacement and a nonlinear increase with the decrease in tip angle. At the same time, we showed that properties contributing to the overall mixing effectiveness of the device can be in “competition” with each other, making the identification of optimal geometric and working configurations nontrivial. For this reason, we believe that our computational effort, in addition to providing better understanding of flow around sharp edges in confined microchannels, is also very useful in design optimization of sharp-edge micro-mixers. The latter have numerous applications in many lab-on-a-chip processes like medical diagnosis, drug delivery, chemical synthesis, and enzyme reactions.44–76 A natural extension of our numerical model would be to include the coupling of the microfluidic channel with the substrate. Our numerical model can also be integrated with a study of the acoustic wave propagation through phononic structures which have been recently demonstrated77–79 as an alternative interface between the substrate and the disposable microfluidic chip to achieve better control of the acoustic wave propagation.
