This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Non-linear optical properties of gold quantum clusters. The smaller the better.

Isabelle Russier-Antoine, Franck Bertorelle, Marin Vojkovic, Driss Rayane, Estelle Salmon, Christian Jonin, Philippe Dugourd, Rodolphe Antoine* and Pierre-François Brevet

By developing a new method for synthesizing atomically monodisperse Au$_{15}$ nanoclusters stabilized with glutathione molecules and using the current state-of-the-art methods for synthesizing monodisperse protected Au$_{25}$ nanoclusters, we investigate their nonlinear optical (NLO) properties after two-photon absorption. The two-photon emission spectra and the first hyperpolarizabilities of these particles were obtained using, in particular, hyper-Rayleigh scattering technique. The influence on NLO of the excitation wavelength, the size as well as the nature of the ligands are also explored and discussed. Au$_{15}$, the smallest stable thiolated gold nanocluster, presents remarkable nonlinear properties with respect to two-photon processes. The TPA cross section at 780 nm for Au$_{15}$ is $\sim 65700$ GM. This experimental cross-section value points to a quantum yield for two-photon emission of about $3 \times 10^{-7}$ at 475 nm for Au$_{15}$. The first hyperpolarizability $\beta$ for Au$_{15}$ clusters ($509 \times 10^{-30}$ esu), as compared to Au$_{25}$ clusters ($128 \times 10^{-30}$ esu) is larger considering the difference in the number of gold atoms. Also, the $10^{-30} \beta$/atom values reported for Au$_{15}$ and Au$_{25}$ clusters are more than two orders of magnitude larger than the values reported for Au NPs in the size range 10-50 nm, outlining the quantum cluster regime.

Introduction

Due to discrete energy levels and molecular-like HOMO-LUMO transitions, ultrasmall clusters exhibit a spectacular optical behavior which is fundamentally different from that of larger plasmonic nanocrystals. Recently, considerable progress has been achieved in the study of the linear and nonlinear optical properties of gold nanoparticles and clusters of varying size and shape. The evolution of nonlinear optical properties, from gold atomic clusters to plasmonic nanocrystals has been addressed by Thomas and co-workers. In particular they showed that the third-order optical nonlinearity in these ultrasmall gold clusters exhibits a significantly lower threshold for optical power limiting. On the other hand, the relatively strong emission under single-photon excitation for Au clusters leads to questions about the possibility of two-photon excited emission. For instance, by measuring two-photon fluorescence excited at 800 nm, Goodson et al. have shown that two-photon absorption (TPA) cross-section increases as the size of small gold clusters increases from 1.1 to 4.0 nm. The TPA cross-section for Au$_{25}$ is 427 000 GM, much larger compared to a typical value of approximately 1 000 GM at 800 nm for organic macromolecules. The large TPA cross sections open the way for applications of such small clusters in optical power limiting, nanolithography, and multiphoton biological imaging. Concerning biological imaging, recent developments in optical imaging techniques, in particular multi-photon excitation microscopy that allows studies of biological interactions at a deep cellular level, has motivated intensive research in developing multi-photon absorption fluorophores. For example, Polavarapu et al. successfully demonstrated the applications of water soluble glutathione small gold clusters for both one and two-photon excitation live cell imaging.

Nonlinear optical (NLO) microscopies (two photon microscopy, TPM or second harmonic imaging microscopy, SHIM) received a tremendous interest for 3D imaging of biological tissues. TPM and SHIM are based on fundamentally different NLO processes, two-photon excited fluorescence (TPEF) and second harmonic generation (SHG), respectively. Therefore, they provide complementary information and can be implemented simultaneously in the same microscope. Whereas TPEF labels give information about molecular distribution, the coherent SHG signal is sensitive to the local non-centrosymmetric organization of the dye molecules and find promising applications for example for the measurement of membrane potential of the neuronal activity of the brain.
While numerous works were devoted to measure the TPA cross-sections of low nuclearity Au clusters, their non-linear susceptibilities were only scarcely explored. Third-order nonlinear optical susceptibilities of monolayer-protected Au$_{25}$ were recently reported as well as the one for Au$_{15}$ in contact with indium tin oxide films. The first hyper-polarizabilities of silver quantum clusters of different sizes (Ag$_{20}$, Ag$_{140}$ and Ag$_{980}$) have been recently measured using hyper-Rayleigh scattering technique. In this paper, we aim at exploring NLO properties of ultra-small gold clusters protected by various functionalized thiols. Based on the current state-of-the-art methods for synthesizing atomically monodisperse protected Au$_{25}$ nanoclusters, and reporting a new method for synthesizing atomically monodisperse Au$_{15}$ nanoclusters stabilized with glutathione molecules, we report the TPE spectra and their first hyper-polarizabilities using hyper-Rayleigh scattering technique. The influence on NLO of the excitation wavelength (between 780 and 900 nm), the size (Au$_{15}$ vs Au$_{25}$) and the nature of the ligands (glutathione vs cysteine) is also explored and discussed.

Results and discussion

Characterization and linear optical properties of as-prepared protected gold clusters. The gold clusters produced by synthesis described in supporting information (see methods section and fig. S1) were characterized by mass spectrometry and optical methods. The monodispersity in term of the size of the prepared gold clusters was verified by ESI-mass spectrometry. An ESI mass spectrum for the protected Au$_{15}$ cluster from solution, and acquired under gentle ESI conditions is shown in Figure 1a. A charge state distribution was observed from [M−4H$^+$]$^{4-}$ through [M−8H$^+$]$^{8-}$. Deconvolution of charge states $4^-$ through $8^-$, and using a multiplicative correlation algorithm, provided a mass of 6928 Da for the intact Au cluster, consistent with the calculated mass of Au$_{15}$SG$_{13}$ (see inset Fig. 1a). Also, PAGE for Au:SG clusters using Tsukuda synthesis and for our synthesis confirms the monodispersity in term of the size of the prepared Au$_{15}$SG$_{13}$ clusters (see inset Fig. 1b). Fig. 1b shows the UV-vis absorption spectra in solution of the synthesized Au$_{15}$SG$_{13}$ clusters. The main feature of the spectrum is a monotonic increase in the electron absorption as the laser wavelength decreases with an onset at ~500 nm and a shoulder observed at ~400 nm. The strong absorption arises from mixed intraband (sp$\rightarrow$sp) and interband (sp$\rightarrow$d) transitions. Fig. 2c displays the photoemission and photoexcitation spectra of Au$_{15}$SG$_{13}$. An emission band centered at ~800 nm is observed and originates from radiative intraband transitions within the sp bands across the HOMO-LUMO gap. The excitation spectrum traces well the profiles of the corresponding absorption spectra (see Fig. 1b and 1c), indicating that the sp intraband excitations are responsible for the photoemission. For comparison, Figs. S2 and S3 show the optical absorption spectra of aqueous solutions of Au$_{25}$SG$_{18}$ and Au$_{25}$Cys$_{18}$ as well as the corresponding ESI spectra. The optical spectra are very similar to those reported in the literature. The main features of the spectra are a monotonic decrease in the absorption as the laser wavelength increases and a broad band on the red side of the spectrum (around 650 nm). Both Au$_{25}$ cluster (protected with glutathione and cysteine) solutions display the two features described...
above. The absorption band on the red side of the spectrum is due to the intraband transition (HOMO–LUMO) derived from sp orbitals of Au\textsuperscript{15, 22} and is systematically observed for protected Au\textsubscript{25} clusters.\textsuperscript{15, 19, 23, 24} The excitation spectra trace well the profiles of the corresponding absorption spectra and an emission band centered at ~800-850 nm is observed and is more intense for Au\textsubscript{25} clusters. Optical spectra in solution are very similar to those reported by Tsukuda and coworkers\textsuperscript{19, 20} on separated band after PAGE separation.

\[ F(t) = \frac{1}{2} \phi \eta_2 N(t) \]  

Where \( N(t) \) is the number of excited molecules, \( \eta_2 \) the quantum efficiency for fluorescence of the molecule and \( \phi \) the collection efficiency of the experimental arrangement. The \( \frac{1}{2} \) factor accounts for the physical reduction by half of the number of photons owing to the two-photon excitation process.

For a pulsed excitation, the number of excited photons is:

\[ N(t) = \sigma_2 C \frac{\beta_3 (P(t))^2}{f \tau \lambda / n} \]  

Where \( \sigma_2 \) is the two-photon absorption (TPA) cross-section, \( C \) the concentration, \( f \) the laser pulse frequency, \( \tau \) the pulse duration, \( \beta_3 \) its second-order coherence function, \( \lambda \) the excitation wavelength, \( n \) the optical index at that frequency and \( <P(t)> \) the incident power averaged over a duty cycle. Using Eqs.(1) and (2), it is experimentally simpler to compare the two-photon excited fluorescence of the sample and that of a known reference compound. Here, we have chosen fluorescein dye as an internal reference. From literature, we assume at the excitation wavelength of 780 nm: \( \sigma_2 \) (fluorescein) = 33.3 GM using a quantum yield of 0.9 and two photon absorption cross-section of 37 GM.\textsuperscript{26} Fluorescein dye was used at the low concentration of 10 \( \mu \)M in order to obtain two-photon emission yields compatible with the Au\textsubscript{15} and Au\textsubscript{25} two-photon yields. In particular, no changes in the experimental settings were performed between the two measurements.

Experimentally, we find for the TPE fluorescence cross section at 475 nm: 0.022 GM for Au\textsubscript{15} but only 0.0022 GM for Au\textsubscript{25} clusters. As expected, for the same excitation wavelength, the TPE fluorescence cross section at 755 nm is only 0.82 GM whereas it is 4.99 GM for Au\textsubscript{25}. Since this cross-section value is rather low, its power dependence with the square of the input laser intensity was checked. Fig. S4 in supporting information shows the fluorescence spectra obtained after excitation at 800 nm and at different pump-powers for Au\textsubscript{15} and pump-power dependence of the fluorescence which gave a slope of ~2 suggesting also that it is indeed a two-photon excited emission. Interestingly, we also measured the TPA cross section at 780 nm for Au\textsubscript{15} and we found \( \sigma \) (TPA, Au\textsubscript{15}SG\textsubscript{13}) = 65700 GM. Detailed TPA experimental arrangement, using a P-scan set-up

---

**Figure 2:** Two-photon emission spectra for Au\textsubscript{25}SG\textsubscript{13} as a function of wavelength for different excitation wavelengths (780, 800, 850 and 900 nm). The huge increases in the right part of the spectra are due to the excitation laser lines (780, 800, 850 and 900 nm).

**Two-photon absorption and emission of as-prepared protected gold clusters.** Two-photon excited fluorescence spectra with excitations ranging from 780 nm to 900 nm have been recorded for Au\textsubscript{15} and Au\textsubscript{25} gold clusters. Spectra are given in Fig. 2. A broad band in the visible range (between 400 and 600 nm) is observed and is more intense for Au\textsubscript{15} clusters than for Au\textsubscript{25} clusters. Fluorescence in the visible region was observed for gold nanoparticles and nanoclusters (in particular Au\textsubscript{25}).\textsuperscript{3, 6} Interestingly a well-defined intense band centered at ~750 nm appears for Au\textsubscript{25} in the near IR region (between 700 nm and 800 nm) and is certainly due to the radiative intraband transitions within the sp bands across the HOMO-LUMO gap reported for protected Au\textsubscript{25} clusters (see also Figs. S2 and S3).\textsuperscript{19, 20} No absorption is observed in the red part of the spectrum for Au\textsubscript{15} clusters (see Figure 1b) which is in agreement with a TPE spectrum dominated by a broad band between 400 nm and 600 nm.

We attempt to determine the two-photon cross-section at 475 nm of gold clusters. The number of fluorescence photons collected in an experiment is given by:\textsuperscript{25}

\[ F(t) = \frac{1}{2} \phi \eta_2 N(t) \]  

Where \( N(t) \) is the number of excited molecules, \( \eta_2 \) the quantum efficiency for fluorescence of the molecule and \( \phi \) the collection efficiency of the experimental arrangement. The \( \frac{1}{2} \) factor accounts for the physical reduction by half of the number of photons owing to the two-photon excitation process.

For a pulsed excitation, the number of excited photons is:

\[ N(t) = \sigma_2 C \frac{\beta_3 (P(t))^2}{f \tau \lambda / n} \]  

Where \( \sigma_2 \) is the two-photon absorption (TPA) cross-section, \( C \) the concentration, \( f \) the laser pulse frequency, \( \tau \) the pulse duration, \( \beta_3 \) its second-order coherence function, \( \lambda \) the excitation wavelength, \( n \) the optical index at that frequency and \( <P(t)> \) the incident power averaged over a duty cycle. Using Eqs.(1) and (2), it is experimentally simpler to compare the two-photon excited fluorescence of the sample and that of a known reference compound. Here, we have chosen fluorescein dye as an internal reference. From literature, we assume at the excitation wavelength of 780 nm: \( \sigma_2 \) (fluorescein) = 33.3 GM using a quantum yield of 0.9 and two photon absorption cross-section of 37 GM.\textsuperscript{26} Fluorescein dye was used at the low concentration of 10 \( \mu \)M in order to obtain two-photon emission yields compatible with the Au\textsubscript{15} and Au\textsubscript{25} two-photon yields. In particular, no changes in the experimental settings were performed between the two measurements.

Experimentally, we find for the TPE fluorescence cross section at 475 nm: 0.022 GM for Au\textsubscript{15} but only 0.0022 GM for Au\textsubscript{25} clusters. As expected, for the same excitation wavelength, the TPE fluorescence cross section at 755 nm is only 0.82 GM whereas it is 4.99 GM for Au\textsubscript{25}. Since this cross-section value is rather low, its power dependence with the square of the input laser intensity was checked. Fig. S4 in supporting information shows the fluorescence spectra obtained after excitation at 800 nm and at different pump-powers for Au\textsubscript{15} and pump-power dependence of the fluorescence which gave a slope of ~2 suggesting also that it is indeed a two-photon excited emission. Interestingly, we also measured the TPA cross section at 780 nm for Au\textsubscript{15} and we found \( \sigma \) (TPA, Au\textsubscript{15}SG\textsubscript{13}) = 65700 GM. Detailed TPA experimental arrangement, using a P-scan set-up
is given in supporting information (see Fig. S5). These experimental cross-section values point to a quantum yield (\(QY = \frac{\sigma_{PE}}{\sigma_{TPA}}\)) for \(\text{Au}_{15}\) of about \(3 \times 10^{-7}\) at 475 nm, in very good agreement with what is expected for such compounds.  

**Hyperpolarizability measurements.** In these experiments where the HRS intensity is collected, the monochromaticity of the second harmonic light generated was always assessed to prevent any spurious contributions from fluorescence. To this end, the HRS intensity for different concentration was normalized against that of the bare solvent. At each concentration, a 20 nm narrow band spectrum around the HRS line was recorded, see Fig. 3. This experimental procedure is deemed necessary to ensure that the process indeed corresponds to the conversion of two photons at the fundamental frequency into one photon at the harmonic frequency. It is observed in particular that the HRS line is located on top of the strong fluorescence background. Two methods are known to remove this fluorescence background, a time-domain and a spectral-domain method. Here the spectral domain method was used owing to the experimental gated photon counting set-up used. The subtraction of the background was then performed by fitting the narrow band spectra with a Gaussian function for the HRS line superposed on a linear function of the wavelength accounting for the fluorescence background. This subtraction procedure is allowed since the two processes, fluorescence and HRS, are incoherent. The HRS intensity is then given by:

\[
\frac{I_{\text{HRS}}}{I_{\text{HRS}}} = \left( \frac{N_w \beta_w^2 + N \beta^2}{N_w \beta_w^2} \right) = 1 + b N \left( \beta_w^2 \right) 
\]

where \(b = \frac{1}{N} \left( \beta_w^2 \right) \)

with the subscripts \(w\) standing for water, the reference solvent used in this experiment. The losses due to absorbance at the fundamental and the harmonic frequency were determined from the separate UV-visible absorption measurements and all data were corrected prior to the analysis. The HRS intensity recorded for different concentrations of \(\text{Au}_{15}\text{SG}_{13}\) in aqueous solution is reported in Fig. 3.

As seen in Eq.(3), it is necessary to know the hyperpolarizability of the bare solvent to determine the hyperpolarizability of the gold clusters. In the present report, we use the value of \(0.087 \times 10^{-30}\) esu for the first hyperpolarizability of the neat water solution. A discussion on this value may be found in a previous work. The hyperpolarizability values obtained for the different solutions are reported in Table 1.

Interestingly \(\text{Au}_{25}\text{SG}_{18}\) and \(\text{Au}_{25}\text{Cy}_{18}\) have similar hyperpolarizability, meaning that the ligands size has only a weak effect on the SH generation. An absolute value of \((0.16 \pm 0.01) \times 10^{-30}\) esu for the first hyperpolarizability of nonaromatic amino acids was reported by Duboisset et al. And by using a collagen like model, the microscopic hyperpolarizability along the peptide bond was evaluated at \((0.7 \pm 0.1) \times 10^{-30}\) esu. It is clear that the huge hyperpolarizabilities reported in this work cannot be accounted by the ligand shell alone (which only would give a contribution of several \(10^{-30}\) esu for the first hyperpolarizability for a fully coherent superposition). The first hyperpolarizability for \(\text{Au}_{15}\) clusters, as compared to \(\text{Au}_{25}\) clusters is also larger considering the difference in the number of gold atoms. Structural theoretical investigations on \(\text{Au}_{15}\text{(SR)}_{13}\) model features staple motifs protecting the \(\text{Au}_{4}\) nucleus. On the other hand, the \(\text{Au}_{25}\) cluster features a centered icosahedral \(\text{Au}_{13}\) core capped by twelve gold atoms that are situated in six pairs around the three mutually perpendicular 2-fold axes of the icosahedron. Both \(\text{Au}_{15}\) and \(\text{Au}_{25}\) structures are expected to have symmetric gold core structures, which preclude any intense SH generation. The nature of staple motifs protecting the gold core and in particular the structuration of Au-S bonds may be different between \(\text{Au}_{15}\) and \(\text{Au}_{25}\) clusters, and may account for enhanced SH signal for \(\text{Au}_{15}\).

---

**Figure 3:** (top panel) HRS intensity versus wavelength for \(\text{Au}_{15}\text{SG}_{13}\) solutions of different concentrations (blue circles). Lines : fit to a Gaussian function superposed on a linearly increasing function of the wavelength. (bottom panel) Plot of the HRS intensity of for \(\text{Au}_{15}\text{SG}_{13}\) as a function of concentration. The continuous lines correspond to the linear adjustment to eq (3).
Also, the 2-photon absorption leads a resonant excitation (around 400 nm). This resonant SH generation is in competition with a vibronic relaxation leading to two-photon emission. Differences in the dynamics of relaxation may also account for the difference of first hyperpolarizability reported for Au$_{15}$ and Au$_{13}$. Finally, we would like to emphasize that the $10^{30}$β/atom values reported for Au$_{15}$ and Au$_{13}$ clusters are more than two order of magnitude larger than the values reported for Au NPs in the size range 10-50 nm (see Fig. 4 and Table S1 in supporting information). $10^{30}$β/atom values decrease drastically with increasing the number of gold atom and there is a saturation-type of behavior for large gold nanoparticles. The results can be explained by the evolution and involvement of interband transitions in smaller clusters, outlining transition of the cluster behavior to a gold nanoparticle behavior possessing strong surface plasmon absorption.

Conclusions

In summary, size-controlled synthesis of monodispersed gold nanoclusters offers the possibility to address non-linear optical properties of ultrasmall gold quantum clusters in solution. Both the size (Au$_{15}$ and Au$_{25}$) and the nature of ligands (glutathione vs cysteine) were varied to fathom their influence on the nonlinear behavior of such low nuclearity gold clusters upon two-photon excitation. Au$_{15}$, the smallest stable thiolated gold nanocluster presents remarkable two-photon nonlinear properties. Au$_{15}$SG$_{13}$ appears to be a good candidate for nonlinear optical microscopies by either two photon microscopy or second harmonic imaging microscopy. The present experimental results provide unique benchmarks for theoretical modeling of NLO properties of such clusters, although the origin of enhanced NLO properties of Au$_{15}$ clusters, as well as the interplay between the cluster core and the interface between ligand shell and the metallic part needs to be clarified. These NLO data are supposed to be highly sensitive to structure of gold clusters and we anticipate that our work could help to unambiguously assign structures for such low nuclearity gold clusters. Works under these lines are currently undertaken in our lab.

Materials and methods

Materials. All the chemicals were commercially available and were used without purification. HAuCl$_4$$•$3H$_2$O, trifluoroacetic acid (TFA), methanol (HPLC grade), acrylamide (98%), bis-acrylamide (98%), glycine, tris(hydroxymethylamino) methylcarboxy methane (TFA), methanol (HPLC grade), acrylamide (98%) and GSH (γ-Glu7Cys7Gly, MW 307) were purchased from Carl Roth. Sodium borohydride (NaBH$_4$) and tetramethyammmonium borohydride ((CH$_3$)$_3$BH$_4$) were purchased from Sigma Aldrich. MilliQ water with a resistivity of 18.2 MΩ cm was used for all experiments.

Preparation of protected gold clusters. The detailed synthesis of Au$_{15}$SG$_{13}$ is available in the supporting information. Briefly, 234 mg of Glutathion (GSH) was dissolved in 35 ml of methanol and 4 ml of tributylamin in a 100 ml balloon. Then 15 ml of ether was added followed by 5ml of a water gold solution (100 mg of HAuCl$_4$•3H$_2$O). Solution was mixed at -10°C during 1 hour and gold salt was reduced by adding tetrabutylammonium borohydride. The solution was kept the night at ambient temperature before being concentrated to a volume of ≈5 ml in a rotary evaporator. The precipitation is induced by adding methanol (5ml) and ether (15ml). Then precipitated was washed to removed unreacted glutathione and unwanted Au$_x$SG$_y$. Protected Au$_{25}$ clusters were synthesizing as described by T. Pradeep and co-workers$^{15}$ for Au$_{25}$SG$_{18}$ and by J. Xie and co-workers$^{16}$ for Au$_{25}$C$_{y}$S$_{y}$.18.

Polyacrylamide gel electrophoresis (PAGE). PAGE separation was carried out by using a vertical gel electrophoresis unit with a size of 0.2 cm × 20 cm × 20 cm. The separating and stacking gels were prepared by acrylamide monomers with the total contents of 35 and 7 wt% (acrylamide/bis-(acrylamide) 94:6), respectively. The eluting buffer consisted of 192 mM glycine and 25 mM tris(hydroxyethylamine). The as-prepared Au(SG) clusters were dissolved in a 15% (v/v) glycerol/water solution (6 mg in 100 µl). The samples solutions were loaded onto the stacking gel (10 µl per well) and eluted for 14 h at a constant voltage mode (150 V) to achieve sufficient separation.
Mass spectrometry. Solutions were diluted without gel separation at a concentration of ~1 mg/mL in H2O, electrosprayed at a flow rate of 10 μL/min and analyzed in negative mode with a linear quadrupole ion trap mass spectrometer (LTQ, Thermo Fisher Scientific, San Jose, CA) with a spray voltage of ~3 kV and a capillary temperature of 100 °C. Other instrument settings were adjusted for each species to optimize the distribution of charge states observed in the mass spectrum. Isotope-resolved mass spectrum were recorded using the ultra zoom scan mode of the instrument (mass resolution ~ 30 000, mass accuracy 0.2 Th). Collision-induced dissociation (CID) was performed using helium gas at a normalized collision energy of 12% for 30 ms.

Absorption and emission measurements. UV–vis spectra in solution were recorded using an AvaSpec-2048 fiber optic spectrometer and an AvA-Light-DH-S deuterium halogen light source. Fluorescence excitation and emission spectra were measured using a Fluoromax-4 Horiba fluorescence spectrophotometer.

HRS and TPE measurements. The light source for the present HRS and TPE experiments was a mode-locked femtosecond Ti:sapphire laser delivering at the fundamental wavelength of 800 nm pulses with a duration of about 140 femtoseconds at a repetition rate of 76 MHz. After passing through a low-pass filter to remove any unwanted harmonic light generated prior to the cell, the fundamental beam of about 300 mW was focused by a microscope objective into a 1 cm spectrophotometric cell containing the aqueous solution. The HRS (or TPE) light was collected at an angle of 90° from the incident direction by a 2.5 cm focal length lens. The second harmonic light was separated from its linear counterpart by a high-pass filter and a monochromator positioned on the second harmonic wavelength. The HRS light was then detected with a photomultiplier tube and the pulses produced counted with a photon counter. The fundamental beam was chopped at about 115 Hz to enable a gated photon counting mode allowing automatic subtraction of the noise level. For TPE signal, a short pass filter with a cut-off wavelength at 750 nm was placed before the monochromator to minimize the light scattering from the excitation beam.
