We report the facile synthesis of arginine-glycine-aspartic acid (RGD) peptide-targeted iron oxide (Fe₃O₄) nanoparticles (NPs) with ultrahigh relaxivity for in vivo tumor magnetic resonance (MR) imaging. In this study, stable polyethyleneimine (PEI)-coated Fe₃O₄ NPs were first prepared by a mild reduction route. The formed aminated Fe₃O₄ NPs with PEI coating were sequentially conjugated with fluorescein isothiocyanate (FI) and polyethylene glycol (PEG)-ERGD segment, followed by acetylation of the remaining PEI surface amines. The thus formed Fe₃O₄@PEI.NHAc-FI-PEG-RGD NPs were characterized via different techniques. We show that the multifunctional RGD-targeted Fe₃O₄ NPs with a mean size of 9.1 nm are water-dispersible, colloidally stable, and hemocompatible and cytocompatible in the given concentration range. With the displayed ultrahigh T₂ relaxivity (550.04 mM⁻¹s⁻¹) and RGD-mediated targeting specificity to αvβ3 integrin-overexpressing cancer cells as confirmed by flow cytometry and confocal microscopy, the developed multifunctional Fe₃O₄@PEI.NHAc-FI-PEG-RGD NPs are able to be used as a highly efficient nanoprobe for targeted MR imaging of αvβ3 integrin-overexpressing cancer cells in vitro and the xenografted tumor model in vivo. Given the versatile PEI amine-enabled conjugation chemistry, the developed PEI-coated Fe₃O₄ NPs may be functionalized with other biological ligands or drugs for various biomedical applications, in particular diagnosis and therapy of different types of cancer.

Introduction

Magnetic iron oxide (Fe₃O₄) nanoparticles (NPs) have attracted considerable interest in different biomedical applications including but not limited to drug and gene delivery, bioluminescence imaging, and hyperthermia. In particular, Fe₃O₄ NPs have been used as contrast agents for magnetic resonance (MR) imaging because they can shorten the T₂ relaxation time of water protons, thus resulting in enhanced imaging contrast and sensitivity. A variety of approaches have been adopted to synthesize Fe₃O₄ NPs for T₂-weighted MR imaging applications such as thermal decomposition, controlled co-precipitation, and hydrothermal synthesis.

For effective biomedical applications, it is important to render the Fe₃O₄ NPs with good colloidal stability through appropriate surface modification. This is because naked Fe₃O₄ NPs are prone to aggregate due to their large surface energy and strong inherent magnetic dipole interaction. Likewise, the Fe₃O₄ NPs should have reactive surface groups, thus having an ability to be further functionalized to have improved biocompatibility, and to have targeting specificity for MR imaging of different biological systems. For instance, Fe₃O₄ NPs can be silanized to render the particles with amine groups, thereby having good colloidal stability and the ability to be further functionalized. In our previous work, we have shown that stable polyethyleneimine (PEI)-coated Fe₃O₄ NPs can be successfully synthesized via a facile hydrothermal approach. The formed PEI-coated Fe₃O₄ NPs can be modified with polyethylene glycol (PEG) to have improved biocompatibility and significantly reduced macrophage cellular uptake, and be modified with targeting ligand folic acid (FA) or hyaluronic acid (HA) for targeted MR imaging of FA receptor- or CD44 receptor-overexpressing cancer cells in vitro and in vivo, respectively. These studies highlight the importance to prepare Fe₃O₄ NPs with reactive surface functional groups for biomedical imaging applications.

Although the Fe₃O₄ NPs synthesized using the hydrothermal approach reported in our previous work can be used for targeted tumor MR imaging, the T₂ relaxivity of the Fe₃O₄ NPs is all smaller than 160 mM⁻¹s⁻¹. For highly sensitive T₂-weighted MR imaging applications, it is always desirable to synthesize Fe₃O₄ NPs with improved T₂ relaxivity. Recently, Yao and coworkers reported a mild reduction route to synthesize Fe₃O₄ NPs that can be enveloped by poly(methylacrylic acid) via photochemical in situ polymerization. Due to the different nature of the synthesis method, we attempted to modify the surface of Fe₃O₄ NPs formed via the mild reduction method for biomedical applications. For targeted tumor MR imaging, Fe₃O₄ NPs have been modified with various ligands such as arginine-glycine-aspartic acid (RGD)
peptide, antibodies, folic acid (FA), hyaluronic acid (HA), and chlorotoxin. Among these ligands, RGD peptide is quite attractive because it can mediate effective targeting of tumor microvasculature and cancer cells such as glioblastomas through binding of the overexpressed $\alpha_\beta_3$ integrin on the cell surface. The prior successes in the synthesis and modification of PEI-coated Fe$_3$O$_4$ NPs lead us to hypothesize that PEI-coated Fe$_3$O$_4$ NPs may also be synthesized using a mild reduction route and be functionalized with RGD peptide for targeted MR imaging of $\alpha_\beta_3$ integrin-overexpressing cancer cells in vitro and in vivo.

In this present study, we utilized a mild reduction method to produce water-dispersible PEI-coated Fe$_3$O$_4$ NPs (Fe$_3$O$_4$@PEI.NH$_2$ NPs) that were sequentially conjugated with fluorescein isothiocyanate (FI) and PEGylated RGD (PEG-RGD), followed by acetylation of the remaining PEI surface amines (Scheme 1). The thus formed multifunctional RGD-targeted Fe$_3$O$_4$ (Fe$_3$O$_4$@PEI.NHAc-FI-PEG-RGD) NPs were characterized via different techniques. To our surprise, the RGD-targeted Fe$_3$O$_4$ NPs displayed ultrahigh relaxivity (up to 550 mM$^{-1}$ s$^{-1}$, see below). Their cytotoxicity and hemocompatibility were evaluated by cell viability assay, cell morphology observation, and hemolysis assay. The RGD-mediated targeting specificity of the particles to $\alpha_\beta_3$ integrin-overexpressing cancer cells, U87MG cells (a human glioma cell line) was confirmed by flow cytometric analysis and confocal microscopic observation. Furthermore, the developed RGD-targeted Fe$_3$O$_4$ NPs were used as a nanoprobe for targeted MR imaging of U87MG cells in vitro and the xenografted U87MG tumor model in vivo. To our knowledge, this is the first report related to the development of RGD-targeted Fe$_3$O$_4$ NPs with ultrahigh relaxivity for tumor MR imaging applications.

**Experimental section**

**Materials**

PEG with one end of carboxyl group and the other end of amine group (NH$_2$-PEG-COOH, Mw = 2000) and PEG monomethyl ether with the other end of carboxyl group (nPEG-COOH, Mw = 2000) were supplied by Shanghai Yanti Biotechnology Corporation (Shanghai, China). Thioltated cyclic RGD peptide (Mw = 690.93) was purchased from GenicBio (Shanghai, China). N-Succinimidyl 6-maleimidohexanoate (6-M), 1-ethyl-3-[3-dimethylaminopropyl] carbodiimide hydrochloride (EDC), FI, and N-hydroxysuccinimide (NHS) were from J&K Chemical Ltd. (Shanghai, China). Ferric chloride hexahydrate (FeCl$_3$·6H$_2$O > 99%), branched PEI (Mw = 25000), ammonia (25%), sodium sulfite, dimethyl sulfoxide (DMSO), triethylamine, acetic anhydride, and all the other chemicals and solvents were acquired from Aldrich (St. Louis, MO). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) was purchased from Shanghai Sangon Biological Engineering Technology & Services Co., Ltd (Shanghai, China). Fetal bovine serum (FBS), Dulbecco's modified Eagle's medium (DMEM), penicillin, and streptomycin were obtained from Hangzhou Jinuo Biomedical Technology (Hangzhou, China). Water used in all experiments with a resistivity higher than 18.2 MΩ-cm was purified by a Milli-Q Plus 185 water purification system (Millipore, Bedford, MA).

**Preparation of PEI-coated Fe$_3$O$_4$ NPs**

PEI-coated Fe$_3$O$_4$ NPs (Fe$_3$O$_4$@PEI.NH$_2$) were synthesized via a mild reduction route in the presence of PEI. In brief, FeCl$_3$·6H$_2$O (1.3 g) dissolved in 20 mL water was placed into a 250-mL three-necked flask. The solution was bubbled with nitrogen atmosphere for 15 min under stirring. Then an aqueous sodium sulfite solution (0.2 g, 10 mL) was dropwise added into the above solution under stirring. After 30 min, an aqueous PEI solution (0.5 g, 5 mL) and 2 mL of ammonia was sequentially added into the above mixture solution. Thereafter, the mixture solution was vigorously stirred for 30 min at 60–70°C. After that, the reaction mixture was cooled down to room temperature and stirred for another 1.5 h. The formed Fe$_3$O$_4$@PEI.NH$_2$ product was magnetically collected and washed several times with water. Finally, the Fe$_3$O$_4$@PEI.NH$_2$ product was centrifuged (8 000 rpm, 10 min) to remove the larger particles, and the supernatant suspension was collected and stored at 4°C before use. For comparison, naked Fe$_3$O$_4$ NPs without coating of PEI were also prepared under similar experimental conditions.

**Synthesis of Fe$_3$O$_4$@PEI.NH$_2$-FI NPs**

The obtained Fe$_3$O$_4$@PEI.NH$_2$ NPs (154 mg) dispersed in water were collected and washed with DMSO for 3 times by virtue of an external magnet, and then re-dispersed in DMSO (10 mL). Then, FI (3.59 mg) dissolved in 1 mL DMSO was dropwise added into the DMSO solution of the Fe$_3$O$_4$@PEI.NH$_2$ NPs under vibration in the dark at room temperature. After 24 h, the formed Fe$_3$O$_4$@PEI.NH$_2$-FI NPs were magnetically collected, purified with DMSO via 3 cycles of magnetic separation/washing/redispersion, and finally re-dispersed in 10 mL DMSO.

**Synthesis of RGD-PEG-COOH**

RGD-PEG-COOH was synthesized according to our previous work. In brief, 6-M (0.012 mmol, 3.70 mg) was first reacted with NH$_2$-PEG-COOH (0.01 mmol, 20 mg) in DMSO (5 mL) at room temperature for 8 h. Then the DMSO solution of RGD (0.01 mmol, 6.91 mg, 2 mL) was dropwise added into the above mixture under vigorous magnetic stirring at room temperature for 12 h. The reaction mixture was then dialyzed against phosphate buffered saline (PBS, 3 times, 2 L) for 1 day and water (3 times, 2 L) for 2 days using a dialysis membrane with molecular weight cut-off (MWCO) of 1 000, followed by lyophilization to obtain the product of RGD-PEG-COOH.

**Synthesis of multifunctional RGD-targeted Fe$_3$O$_4$ NPs**

RGD-PEG-COOH (8.338 mmol, 25 mg), EDC (83.411 mmol, 15.99 mg), and NHS (83.413 mmol, 9.60 mg) were dissolved in 2 mL DMSO, respectively. Then all the three solutions were mixed and stirred for 3 h to activate the carboxyl group of RGD-PEG-COOH. The activated RGD-PEG-COOH was dropwise added into the above DMSO solution of Fe$_3$O$_4$@PEI.NH$_2$-FI NPs (10 mL) under stirring for 3 days.

The formed Fe$_3$O$_4$@PEL.NH$_2$-FI-PEG-RGD were collected and washed with DMSO for 1 time and water for 3 times to remove...
excess reactants via magnetic separation, and dispersed in 10 mL water. The remaining PEI amines on the surface of the formed Fe₃O₄@PEI.NH₂-PEG-RGD NPs were further acetylated according to our previous reports.²⁹, ³⁰ Briefly, triethylamine (505 μL) was first dropwise added into the Fe₃O₄@PEI.NH₂-PEG-RGD aqueous suspension (10 mL) and the solution was well mixed via shaking for 30 min. Then, acetic anhydride (412 μL) was dropwise added into the Fe₃O₄@PEI.NH₂-PEG-RGD/triethylamine mixture solution under vigorous shaking in the dark for another 24 h. Finally, the product was purified via 3 cycles of magnetic separation/washing/redispersion in water. The formed Fe₃O₄@PEI.NH₂c-PEG-RGD NPs were dispersed in water (10 mL) and stored at 4 °C for further use. For comparison, non-targeted Fe₃O₄ NPs without RGD conjugation (Fe₃O₄@PEI.NH₂-mPEG NPs) were also prepared in a manner similar to that used to form the Fe₃O₄@PEI.NH₂-PEG-RGD NPs. The only difference is the use of mPEG-COOH instead of the use of RGD-PEG-COOH.

Characterization techniques

¹H NMR spectra were collected using a Bruker AV400 nuclear magnetic resonance spectrometer. Samples were dissolved in deuterated DMSO (DMSO-d₆) before measurements. UV-Vis spectroscopy was undertaken using a Lambda 25 UV-Vis spectrophotometer (PerkinElmer, Boston, MA), and samples were dispersed in water before measurements. Zeta potential and dynamic light scattering (DLS) measurements were performed using a Malvern Zetasizer Nano ZS model ZEN3600 (Worcestershire, UK) equipped with 633 nm laser. Samples were dispersed in water at a concentration of 0.1 mg/mL before measurements. Thermal gravimetric analysis (TGA) was performed at a heating rate of 20 °C/min to quantify the composition of samples using a TG 209 F1 (NETZSCH Instruments Co., Ltd., Germany) thermogravimetric analyzer operating in a temperature range of 25–700 °C under flowing nitrogen atmosphere. Transmission electron microscopy (TEM, JEOL 2010F analytical electron microscope, Tokyo, Japan) was carried out to characterize the size and morphology of the NPs at an accelerating voltage of 200 kV. TEM samples were prepared by depositing a dilute particle suspension (5 μL) onto a carbon-coated copper grid and air dried before measurements. For each sample, more than 300 NPs in different TEM images were randomly selected and measured using an ImageJ software to assess the average size and size distribution of the NPs. Leeman Prodigy inductively coupled plasma-optical emission spectroscopy (ICP-OES, Hudson, NH) was used to measure the Fe concentration of the NP suspension. T₂ relaxometry was performed using a 0.5 T NMR20- Analyst NMR Analyzing system (Shanghai Niumag Corporation, Shanghai, China). Samples were diluted in water with Fe concentration in a range of 0.003–0.048 mM before measurements. The instrumental parameters were set as follows: point resolution = 156 mm × 156 mm, section thickness = 0.6 mm, TR = 4000 ms, TE = 60 ms, and number of excitation = 1. The T₂ relaxivity (r₂) was calculated by linear fitting of 1/T₂ (s⁻¹) as a function of Fe concentration (mM).

Hemolysis assay

Fresh human blood stabilized with ethylenediaminetetraacetic acid (EDTA) was obtained by Shanghai First People’s Hospital (Shanghai, China) and used after approval by the Shanghai First People’s Hospital Ethical Committee. The human red blood cells (HRBCs) were purified according to our previous work.⁴⁴, ⁴⁵ Then, the suspension of HRBCs was 10 times diluted with PBS. The diluted HRBC suspension (0.1 mL) was added into 0.9 mL water as a positive control, 0.9 mL PBS as a negative control, and 0.9 mL PBS containing RGD-targeted Fe₃O₄ NPs or non-targeted Fe₃O₄ NPs at different Fe concentrations (0.5–8.0 mM), respectively. The mixtures were gently vortexed and then kept still for 2 h at room temperature. After centrifugation at 10 000 rpm for 1 min, the photos of the samples were taken and the absorbance of the supernatants (hemoglobin) was recorded by a Perkin Elmer Lambda 25 UV-Vis spectrophotometer. The hemolysis percentages of different samples were calculated according to a previously reported method.⁶, ¹⁸, ⁴³

Cytotoxicity assay and cell morphology observation

U87MG cells overexpressing α₅β₃ integrin were routinely cultured and passaged in 25-cm² plates in regular DMEM supplemented with 10% heat-inactivated FBS, penicillin (100 U/mL), and streptomycin (100 μg/mL) in a 37 °C incubator with 5% CO₂.

In vitro cytotoxicity of the RGD-targeted Fe₃O₄ NPs and non-targeted Fe₃O₄ NPs were evaluated by MTT viability assay of U87MG cells. Briefly, 1×10⁵ U87MG cells were seeded with 200 μL of DMEM per well into a 96-well plate and cultured at 37 °C and 5% CO₂ overnight to bring the cells to confluence. Then the medium was replaced with 200 μL fresh medium containing PBS (control), RGD-targeted Fe₃O₄ NPs or non-targeted Fe₃O₄ NPs at different Fe concentrations (10, 25, 50, 75, and 100 μg/mL, respectively). After incubation at 37 °C and 5% CO₂ for 24 h, MTT (20 μL in PBS, 5 mg/mL) was added to each well and the cells were incubated under the same culture conditions for an additional 4 h. After that, DMSO (150 μL) was added to replace the culture medium and to dissolve the insoluble formazan crystals. The assays were carried out according to the manufacturer’s instructions and the absorbance of each well was recorded using a Thermo Scientific Multiskan MK3 ELISA reader (Thermo scientific, Hudson, NH) at 570 nm. Mean and standard deviation (SD) of 5 parallel wells for each sample were reported. To further confirm the cytotoxicity of the RGD-targeted and non-targeted Fe₃O₄ NPs, the morphology of U87MG cells treated with the NPs at different Fe concentrations (10, 25, 50, 75, and 100 μg/mL, respectively) for 24 h was also observed by phase contrast microscopy (Leica DM IL LED inverted phase contrast microscope) with a magnification of 200 × for each sample.

Flow cytometry

U87MG cells were seeded in 12-well plates at a density of 2 × 10⁵ cells per well in 1 mL of DMEM and incubated at 37 °C and 5% CO₂ overnight to bring the cells to confluence. Then the medium was replaced with 1 mL fresh medium containing PBS, RGD-targeted Fe₃O₄ NPs or non-targeted Fe₃O₄ NPs at different Fe concentrations (0.125, 0.25, 0.50, 1.00, and 1.50 mM, respectively). After 4 h incubation at 37 °C and 5% CO₂, the cells were washed 3 times with PBS, trypsinized, centrifugated, and resuspended in 1 mL PBS before flow cytometry analysis using a FACSCalibur flow cytometer (Becton-Dickinson, Franklin

This journal is © The Royal Society of Chemistry [year]

Journal Name, [year], [vol], oo–oo | 3
The FL1-fluorescence of 10,000 cells was measured and the measurement of each sample was repeated for 3 times. For comparison, U87MG cells were first incubated with free RGD (2 μM) for 1 h to block the overexpression of αvβ3 integrin. The free RGD-blocked U87MG cells were also treated with the RGD-targeted Fe3O4 NPs at different Fe concentrations and analyzed under similar experimental conditions.

Confocal microscopy

Confocal microscopy (Carl Zeiss LSM 700, Jena, Germany) was carried out to confirm the RGD-mediated specific cellular uptake of the multifunctional Fe3O4 NPs. In brief, cover slips were first treated and fixed in a 12-well tissue culture plate according to our previous report.4 U87MG cells were then seeded into the culture plate at a density of 2 \times 10^5 cells/well with 1 mL fresh medium and cultured at 37 °C and 5% CO2 overnight to leave the cells well attached onto the cover slips. Then, the medium was replaced with 1 mL fresh medium containing PBS (control), RGD-targeted Fe3O4 NPs or non-targeted Fe3O4 NPs at an Fe concentration of 0.5 mM. After incubation at 37 °C and 5% CO2 for 4 h, the cells were rinsed with PBS for 3 times, fixed with glutaraldehyde (2.5%) for 15 min at 4 °C, and counterstained with Hoechst 33342 (1 mg/mL) for 15 min at 37 °C using a standard procedure. The cells on the coverslips were imaged using a 63 × oil-immersion objective lens. U87MG cells blocked with free RGD (2 μM) for 1 h were also imaged in a similar manner for comparison.

In vitro MR imaging of cancer cells

U87MG cells were seeded into a 6-well plate at a density of 3 \times 10^5 cells per well with 2 mL DMEM and incubated at 37 °C and 5% CO2 overnight to bring the cells to confluence. Then the medium was replaced with 2 mL fresh medium containing PBS (control), RGD-targeted Fe3O4 NPs, or non-targeted Fe3O4 NPs at different Fe concentrations (0.1, 0.2, 0.3, and 0.4 mM, respectively). After incubation at 37 °C and 5% CO2 for another 6 h, the cells were rinsed with PBS for 5 times, trypsinized, centrifuged, and resuspended in 1 mL PBS (containing 0.5% agarose) in 2-mL Eppendorf tubes before MR imaging. T2-weighted MR imaging of the cell suspensions was performed by a 3.0 T Signa HDxt superconductor clinical MR system (GE Medical Systems, Milwaukee, WI) with 2 mm slice thickness, 95% water and 5% fat. U87MG cells blocked with free RGD (2 μM) for 1 h were also imaged in a similar manner for comparison.

In vivo MR imaging of a xenografted tumor model

Animal experiments were carried out according to protocols approved by the institutional committee for animal care, and also in accordance with the policy of the National Ministry of Health. To establish the xenografted tumor model, male 4- to 6-week-old BALB/c nude mice (15-20 g, Shanghai Slac Laboratory Animal Center, Shanghai, China) were subcutaneously injected with 3 \times 10^6 cells/mouse in the right hind legs. When the tumor nodules reached a volume of 0.8-1.6 cm^3 at about 3 weeks postinjection, the mice were anesthetized by intraperitoneal injection of pentobarbital sodium (40 mg/kg), and then the RGD-targeted or non-targeted Fe3O4 NPs were intravenously injected into the nude mice via the tail vein (600 μg Fe per mouse, in 0.1 mL PBS). After placing the mice inside a custom-built rodent receiver coil (Chenguang Med Tech, Shanghai, China), MR scanning of the mice was carried out before and after administration of the RGD-targeted or non-targeted Fe3O4 NPs at the time points of 0.5, 1, 2, 4, and 24 h postinjection using a 3.0 T Sigma HDxt superconductor clinical MR system under similar conditions to those used for in vitro MR imaging of cancer cells.

In vivo biodistribution

To assess the biodistribution of the multifunctional Fe3O4 NPs, the above tumor-bearing BALB/c nude mice after MR scanning at 24 h post-injection were euthanized and the major organs including the heart, liver, spleen, lung, kidney and tumor were extracted and weighed. The organs were cut into small pieces and digested by aqua regia (nitric acid/hydrochloric acid, v/v = 1:3) for 2 days before ICP-OES quantification of the Fe element. For comparison, the tumor-bearing mice injected with PBS (0.1 mL) were used as control.

Statistical analysis

One-way ANOVA statistical analysis was performed to evaluate the significance of the experimental data. 0.05 was selected as the significance level, and the data were indicated with (*) for p < 0.05, (**) for p < 0.01, and (***) for p < 0.001, respectively.

Results and discussion

Synthesis and characterization of Fe3O4@PELNH2A-PEG-RGD NPs

By adopting a mild reduction route reported by Yao and coworkers,30 PEI-coated Fe3O4 NPs were synthesized by reduction of Fe(NO3)3 in the presence of PEI. The PEI-coated Fe3O4 NPs (Fe3O4@PEL.NH2 NPs) were then sequentially modified with Fl via a thiourea linkage and PEGylated RGD via EDC chemistry, followed by acetylation of the remaining PEI surface amines (Scheme 1). The thus formed multifunctional RGD-targeted Fe3O4 NPs were characterized via different techniques.

The modification of Fl moiety onto the surface of the Fe3O4@PEL.NH2 NPs was confirmed by UV-Vis spectroscopy (Figure S1, Electronic Supplementary Information, ESI). Apparently, the appearance of a prominent absorption peak at 500 nm suggests the successful conjugation of Fl onto the particles, in agreement with our previous work.3 In contrast, no significant absorption feature can be seen at the same wavelength for the Fe3O4@PEL.NH2 NPs without Fl modification.

To modify RGD onto the surface of the Fe3O4@PEL.NH2 NPs, PEGylated RGD (RGD-PEG-COOH) was firstly synthesized by reacting the heterofunctional NH2-PEG-COOH with 6-M to render the PEG with maleimide end group for subsequent coupling with thiolated RGD via thiol maleimide coupling.40 The formed RGD-PEG-COOH segments were characterized by 1H NMR spectroscopy (Figure S2, ESI). Through the NMR integration of the RGD-associated aromatic proton peaks at 7.3 and 7.4 ppm and the PEG methylene proton at 3.7 ppm, the average number of RGD conjugated to each PEG was estimated to be 0.5. Next, the formed Fe3O4@PEL.NH2-Fl NPs were modified with RGD-PEG-COOH or mPEG-COOH through EDC chemistry, and were quantitatively characterized by TGA (Figure 1). Clearly, the Fe3O4@PEL.NH2-Fl NPs have a weight loss of 12.4% due to the coating of PEI and the modification with Fl. After further modification with RGD-PEG-COOH or mPEG-
COOH, the weight losses of Fe₃O₄@PEI.NH₂-FI-PEG-RGD and Fe₃O₄@PEI.NH₂-FI-mPEG NPs were estimated to be 16.4% and 15.7%, respectively. Hence, the RGD-PEG-COOH and mPEG-COOH modified onto the surface of the Fe₃O₄@PEI.NH₂-FI NPs were calculated to be 4.0% and 3.3%, respectively.

Zeta potential and hydrodynamic size of each NP product were measured to confirm each step surface modification (Table 1). Clearly, naked Fe₃O₄ NPs without PEI coating have a relatively large particle size of 537.9 nm, which is due to the lack of PEI stabilization and their surface potential was measured to be -8.3 mV. In contrast to the naked Fe₃O₄ NPs, the PEI coating is able to afford the formed Fe₃O₄@PEI.NH₂ NPs with decreased hydrodynamic size (71.6 nm) and with a quite positive surface potential (+64.7 mV). To further render the particles with improved cytocompatibility and non-specific cell membrane binding, it’s necessary to neutralize the remaining PEI surface amines on the particle surfaces, similar to our previous reports. This should be noted that the positive surface potential of the PEI amines on the particle surfaces. After acetylation reaction, the surface potential of the formed Fe₃O₄@PEI.NHAC-FI-PEG-RGD and Fe₃O₄@PEI.NHAC-FI-mPEG NPs are quite positively charged with surface potential of +59.2 and +54.1 mV, respectively due to the existence of a large amount of remaining PEI amines on the particle surfaces. After acetylation reaction, the surface potential of the formed Fe₃O₄@PEI.NHAC-FI-PEG-RGD and Fe₃O₄@PEI.NHAC-FI-mPEG NPs were measured to be +28.3 and +26.4 mV, respectively. The decreased surface potential for both NPs confirmed the success of the acetylation reaction. It is clear that the positive surface potential of the NPs is not able to be completely neutralized in the presence of excess acetic anhydride. This could be due to that fact that a portion of the PEI amines used to stabilize the Fe₃O₄ NPs cannot be acetylated, in good agreement with our previous reports.

The hydrodynamic size of the formed NPs was determined by DLS (Table 1). It is clear that the Fe₃O₄@PEI.NH₂-FI-PEG-RGD, Fe₃O₄@PEI.NH₂-FI-mPEG, Fe₃O₄@PEI.NHAC-FI-PEG-RGD and Fe₃O₄@PEI.NHAC-FI-mPEG NPs have a hydrodynamic size of 126.2 nm, 108.9 nm, 146.5 nm, and 127.3 nm, respectively. It appears that the acetylation reaction of the remaining PEI surface amines does not appreciably affect their hydrodynamic size. For biomedical applications, the formed targeted and non-targeted NPs should possess a good colloidal stability. The hydrodynamic size of the targeted and non-targeted NPs was occasionally checked by DLS within a time period of 2 weeks (Figure S3, ESI). We show that the hydrodynamic sizes of both NPs do not have appreciable changes, suggesting their good colloidal stability. The colloidal stability of both particles was also assessed by exposing them to water, PBS, and cell culture medium for one month. We show that both NPs are colloidal stable and no precipitation occurs (Figure S3, inset, ESI), further confirming their excellent colloidal stability.

TEM was used to characterize the size and morphology of the formed RGD-targeted Fe₃O₄ NPs (Figure 2a) and non-targeted Fe₃O₄ NPs (Figure 2b). It is clear that most of the particles display a spherical or quasi-spherical shape with a relatively uniform size distribution. The mean diameters of the targeted and non-targeted Fe₃O₄ NPs were measured to be 9.1 ± 1.9 nm and 9.0 ± 1.7 nm, respectively. It is worth noting that the measured particle size for each NP by TEM is much smaller than that measured by DLS. This can be ascribed to the fact that TEM measures the size of a single particle, while DLS measures the size of particle clusters dispersed in aqueous solution that may consist of many single particles.

**T₂ relaxometry**

The transverse relaxation time (T₂) of water protons in an aqueous solution of the formed RGD-targeted and non-targeted Fe₃O₄ NPs was measured at 0.5 T to explore their potential for MR imaging applications. From the T₂-weighted MR images (Figure 3a), it can be seen that both NPs are able to decrease the MR signal intensity with the increase of Fe concentration. By plotting the relaxation rate (1/2T₂) as a function of the Fe concentration, the T₂ relaxivity of the RGD-targeted and non-targeted Fe₃O₄ NPs was calculated to be 550.04 and 545.70 mM⁻¹ s⁻¹, respectively (Figure 3b). Interestingly, both NPs display a much higher T₂ value than other Fe₃O₄ NPs prepared by hydrothermal approach or co-precipitation route, rendering them with an ability for highly sensitive T₂-weighted MR imaging applications. The exact mechanism related to the ultrahigh T₂ relaxivity is still unclear. It may be due to the nature of the mild synthesis method that can generate particles with extremely high magnetic dipole interaction.

**Cytotoxicity assay and cell morphology observation**

Next, the cytotoxicity of the formed RGD-targeted and non-targeted Fe₃O₄ NPs was evaluated by MTT cell viability assay (Figure 5). It can be seen that the viability of the U87MG cells is higher than 80% after treatment with either RGD-targeted or non-targeted Fe₃O₄ NPs in the given Fe concentration range (0.1-100 μg/mL), suggesting their good cytocompatibility. The cytocompatibility of both NPs were further evaluated by phase contrast microscopic observation of the cells treated with the particles at different Fe concentrations (10, 25, 50, 75, and 100 μg/mL) for 24 h (Figure S5, ESI). It is clear that the treated U87MG cells do not display any appreciable morphological
changes when compared with the control cells treated with PBS (Figure S5a and S5g) even at the Fe concentration of 100 μg/mL (Figure S5f and S5i). The cell morphology observation corroborates the MTT assay data, suggesting that both NPs are non-cytotoxic in the given concentration range.

Flow cytometry assay

To explore the RGDE-mediated targeting specificity of the multifunctional Fe₃O₄ NPs, flow cytometry assay of the U87MG cells was performed by virtue of the green fluorescence associated to the attached FI moiety (Figure S6, ESI). Clearly, U87MG cells treated with the non-targeted Fe₃O₄ NPs and free RGD-blocked U87MG cells treated with the RGDE-targeted Fe₃O₄ NPs display much lower fluorescence signal intensity than the U87MG cells treated with the RGDE-targeted Fe₃O₄ NPs at the same Fe concentrations. This can also be reflected by the quantification of the mean fluorescence of the U87MG cells (Figure 6). The significantly high fluorescence signal intensity of the U87MG cells treated with the RGDE-targeted Fe₃O₄ NPs implies that the attached RGD ligands onto the particles are able to mediate the specific targeting of the particles to αᵥβ₃ integrin-overexpressing U87MG cells, in agreement with the literature.37

The increased cellular uptake of the non-targeted Fe₃O₄ NPs by U87MG cells and targeted Fe₃O₄ NPs by the free RGD-blocking U87MG cells with the Fe concentration may be ascribed to two different mechanisms: phagocytosis and diffusion via cell walls.18, 22, 48, 49

Confocal microscopy

The modification of FI moiety onto the surface of the Fe₃O₄ NPs also enabled confocal microscopic tracking of the intracellular localization of the particles. Figure 7 shows the confocal microscopic images of the U87MG cells treated with PBS, RGD-targeted Fe₃O₄ NPs, or non-targeted Fe₃O₄ NPs at the Fe concentration of 0.5 mM for 4 h, respectively. For comparison, free RGD-blocked U87MG cells were also tested under similar instrumental conditions. Clearly, the free RGD-blocked U87MG cells treated with RGD-targeted Fe₃O₄ NPs (Figure 7b), the U87MG cells treated with the non-targeted Fe₃O₄ NPs (Figure 7c) do not show apparent fluorescence signals, which is similar to the control cells treated with PBS (Figure 7a). In sharp contrast, only the U87MG cells treated with the RGD-targeted Fe₃O₄ NPs display prominent green fluorescent signals in the cytosol and on the cell surfaces, which is associated with the cellular uptake of the particles labeled with the FI moiety (Figure 7d). These results clearly indicate that the specific binding and uptake of the RGD-targeted NPs should be mediated by the αᵥβ₃ integrin receptors overexpressed on the cell surfaces, in good agreement with the results of flow cytometry assay.

Targeted MR imaging of cancer cells in vitro

With the proven targeting specificity of the RGD-targeted Fe₃O₄ NPs and the ultrahigh T₂ relaxivity, we next explored the potential to use them as a nanoprobe for targeted MR imaging of cancer cells in vitro. T₂-weighted MR images of the U87MG cells treated with either RGD-targeted or non-targeted Fe₃O₄ NPs at different Fe concentrations (0.1, 0.2, 0.3, and 0.4 mM, respectively) were obtained (Figure 8a) and the signal intensity of the cells was quantified (Figure 8b). It is clear that both NPs are able to decrease the MR signal intensity of the cells with the Fe concentration. However, the decreasing trend of the MR signal intensity of the U87MG cells treated with the RGDE-targeted Fe₃O₄ NPs is much more significant. This can be further clearly reflected by quantitative analysis of the MR signal intensity of the cells as a function of Fe concentration (Figure 8b). Apparently, the signal intensity of the U87MG cells treated with the RGDE-targeted Fe₃O₄ NPs is much lower than that treated with the non-targeted Fe₃O₄ NPs at each tested Fe concentration (p < 0.001). These results suggest that the developed multifunctional Fe₃O₄ NPs can be used as a promising nanoprobe for targeted MR imaging of αᵥβ₃ integrin-overexpressing cancer cells in vitro.

In vivo MR imaging of U87MG tumor model

We next applied the developed multifunctional Fe₃O₄ NPs as a nanoprobe for targeted MR imaging of a xenografted tumor model in vivo. Non-targeted Fe₃O₄ NPs were also used for comparison. The T₂-weighted MR images of the tumors were colored to allow easy differentiation of the contrast enhancement (Figure 9). From Figure 9a, we can see that the tumor MR signal of all mice gradually decreases with the time postinjection, which is due to the fact that the particles are able to be gradually accumulated into the tumor sites. At 1 h postinjection, both particles are able to induce the weakest tumor MR signal intensity. At 2 h postinjection, the tumor MR signal intensity starts to recover, presumably because the particles have undergone a further metabolism process and a portion of the particles are able to escape from the tumor site. Clearly, the tumor MR signal intensity after treated with the RGDE-targeted Fe₃O₄ NPs is much lower than that after treated with the non-targeted Fe₃O₄ NPs at the same time point postinjection of the respective particles. This can be further validated by quantifying the MR signal intensity as a function of the time postinjection of the particles (Figure 9b). The tumor MR signal intensity after injection of the RGDE-targeted Fe₃O₄ NPs is significantly lower than that after injection of the non-targeted Fe₃O₄ NPs at 0.5, 1, 2, and 4 h postinjection, respectively (p < 0.05). At 24 h postinjection, the tumor MR signal of the mice treated with either RGD-targeted or non-targeted Fe₃O₄ NPs recovers to some extent. Our results suggest that the developed multifunctional Fe₃O₄ NPs are able to be used a nanoprobe for targeted MR imaging of tumors through RGDE-mediated targeting pathway.

In vivo biodistribution

For in vivo biomedical imaging applications, it’s important to understand the biodistribution behavior of the developed multifunctional Fe₃O₄ NPs. ICP-OES was performed to analyze the accumulation of RGD-targeted or non-targeted Fe₃O₄ NPs in several major organs including the heart, liver, spleen, lung, kidney, and tumor at 24 h postinjection (Figure S7, ESI). It is clear that the Fe concentration in the liver, spleen and lung of the mice treated with either non-targeted or RGD-targeted Fe₃O₄ NPs is much higher than that of the control mice treated with PBS. In addition, a smaller amount of uptake can also be found in the heart, kidney and tumor tissue. Our results suggest that both Fe₃O₄ NPs can be excreted from the living body at 24 h postinjection, in agreement with the MR imaging data.

Conclusion
In summary, we developed a facile approach to synthesizing multifunctional RGDE peptide-targeted Fe$_3$O$_4$ NPs with ultrahigh r$_2$ relaxivity for MR imaging of tumors. The mild reduction route enabled the synthesis of PEI-coated Fe$_3$O$_4$ NPs that can be further conjugated with FITC and PEGylated RGDE via PEI amine-mediated conjugation chemistry. The formed multifunctional Fe$_3$O$_4$ NPs possess good water dispersibility, colloidal stability, and cytocompatibility and hemocompatibility in the given Fe concentration range. With the demonstrated ultrahigh r$_2$ relaxivity (550.04 mM$^{-1}$s$^{-1}$) and the RGDE-mediated targeting specificity to $\alpha_v\beta_3$ integrin-overexpressing cancer cells, the developed multifunctional RGDE-targeted Fe$_3$O$_4$ NPs are able to be used as an efficient nanoprobe for targeted MR imaging of $\alpha_v\beta_3$ integrin-overexpressing cancer cells in vitro and the xenografted tumor model in vivo. Taking into the consideration of the PEI amine-enabled conjugation chemistry, the PEI-coated Fe$_3$O$_4$ NPs may be further functionalized with anticancer drugs or other targeting ligands, thereby providing a unique nanoplatform for targeted MR imaging and therapy of different types of cancer.
