This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
A New Aluminium-ion Battery with High Voltage, High Safety and Low Cost

Haobo Sun, a Wei Wang, a Zhijing Yu, a Yan Yuan, a Shuai Wang a and Shuqiang Jiao*
a

A new kind of Al-ion battery with carbon paper as cathode, high-purity Al foil as anode and ionic liquid as electrolyte is proposed in this work. The significance of the presented battery is going to be an extremely high average voltage plateau of ca. 1.8 V vs Al\textsuperscript{3+}/Al). Li-ion batteries have been extensively investigated due to their excellent energy and power density. However, the disadvantages are obvious, including cost, lithium resource, reliability, and safety.\textsuperscript{1-4} Owing to the natural abundance and low cost of aluminium, Al-based batteries have become one of the candidates for energy storage devices.\textsuperscript{5-11} Al-air battery system has been investigated for years, however, due to the fast corrosion and hydrogen evolution reaction between aluminium and electrolyte, the utilization of the electrode is reduced, even leading to the scrappage of the battery.\textsuperscript{12-15} Recently, Al-ion battery with multivalent metal ions transmitting internally has attracted much attention, such as VO_2,\textsuperscript{5} V_2O_5,\textsuperscript{6} anatase TiO_2 in aqueous solution,\textsuperscript{7} fluorinated natural graphite,\textsuperscript{8} polymers, Copper hexacyanoferrate,\textsuperscript{10} and prussian blue analogs.\textsuperscript{11} However, none of them is satisfactory for their low capacity, low voltage plateau or short cycle life. We established a new kind of Al-ion battery with a high average voltage plateau and proposed a new theory — “multi-coordination ions/single ions intercalation and deintercalation”.

The detailed experimental methods are shown in the Supplementary Information. The main idea of Al-ion battery is described in Fig. 1. The corresponding experimental photographs are also displayed in Fig. S1a-e (Supplementary Information). All electrochemical reactions occur in the sealed Teflon electrolytic tank. In our device, aluminium foil serves as anode material. At the same time, carbon paper (Fig. 4(d) shows it is composed of graphite) serves as cathode material. Conventional Li-ion and Na-ion batteries can only transfer one charge in one redox couple (Li\textsuperscript{+}/Li or Na\textsuperscript{+}/Na), while Al-ion batteries can transfer three charges in one redox couple (Al\textsuperscript{3+}/Al), which can achieve more gravimetric capacity and volumetric capacity than Li-ion and Na-ion batteries.\textsuperscript{3,6,16} The electrolyte is the mixture of AlCl_3 and 1-ethyl-3-methylimidazolium chloride ([EMIm]Cl) with 1.3:1 molar ratio. In the discharge process, Al metal is oxidized and escapes from Al foil to form Al\textsuperscript{3+}. Under the influence of the electric field, Al ions move to the cathode side. Then

![Fig. 1 Schematic representation of aluminium-based full-battery system during charge and discharge process.](image-url)
In the charge process,

\[\text{Al}^{3+} + 3\, e^- \rightarrow \text{Al} \quad \text{(anode)} \quad (1)\]

\[\text{AlCl}_3 - e^- \rightarrow \text{Al}^{3+} + [\text{AlCl}_3]^- \quad \text{(cathode)} \quad (2)\]

In the discharge process,

\[\text{Al} - 3\, e^- \rightarrow \text{Al}^{3+} \quad \text{(anode)} \quad (3)\]

\[\text{Al}^{3+} + [\text{AlCl}_3]^- + e^- \rightarrow \text{AlCl}_3 \quad \text{(cathode)} \quad (4)\]

The mechanism of this kind of Al-ion full battery is similar to \textit{``rocking-chair''} Li-ion batteries. However, two kinds of ions participate in the reactions during charge and discharge process, i.e., \textit{Al}" and \textit{[AlCl$_3$]}. Thus, a new theory in the charge and discharge process — \textit{``multi-coordination ions/single ions intercalation and deintercalation''} is proposed. In the following sections, we will provide morphology and electrochemical testing proofs to support this assumption.

![Figure 2](image)

**Fig. 2(a)** Cyclic voltammetry curve of Al-ion full battery and that of Mo. The inset is the CV curve of Mo without carbon paper. (b) Charge and discharge curves under different current densities. (c) 1st, 50th and 100th charge/discharge curves at 100 mA g$^{-1}$. (d) Cycling performances of Al-ion full battery under different current densities over 50 cycles.

Fig. 2(a) shows the CV curve of Al-ion battery for the initial three cycles. It should be mentioned that before the batteries are tested, we let them sit overnight. The initial CV curve differs from the other curves, which could be attributed to the volume adjustment of the graphite in the initial cycle and some side reactions, making the graphite layers more suitable for the intercalation and deintercalation of coordination ions. The second and third curves exactly coincide with each other, demonstrating a highly reversible electrochemical reaction. Three obvious reduction peaks can be seen at ca. 1.65 V (a peak), 1.77 V (b peak) and 2.0 V (c peak), respectively. Also, the corresponding oxidation peaks are found at 2.10 V (a' peak), 2.24 V (b' peak) and 2.34 V (c' peak), respectively. The polarization voltage of this battery could be mainly caused by the following reasons: (1) the ionic diameter of Al ions and coordination ions is fairly large, which could inhibit the diffusion of these ions in the electrolyte and the intercalation and deintercalation in the graphite layers (2) the passivation film of Al foil in the anode side may also restrain the deposition and dissolution of Al. To study the influence of the Mo current collector and the electrochemical reactions of the electrolyte, the CV image of Mo is shown in Fig. 1(a). When compared with the battery, the CV curve of Mo is nearly straight. To see it more clearly, the CV curve of Mo is magnified in the inset. Obvious redox peaks at 1.73 V and 1.85 V can be seen, which agrees well with that of the battery. It can be deduced that similar redox reactions occur on the interface of both Mo and C electrode. Whereas the current density of graphite is hundreds of times than that of Mo, and hence, the influence of Mo in this battery system can be ignored. In other words, the redox reaction only occurs on the interface of the graphite-electrolyte.

![Figure 2](image)

**Fig. 2(b)** shows the charge and discharge curves under different current densities from 50 mA g$^{-1}$ to 150 mA g$^{-1}$. The cut-off voltages were set in the range of 0.4–2.35 V vs Al$^{3+}$/Al. Both charge and discharge voltage plateaus can be seen obviously and the average voltage plateau for discharge process is as high as ca. 1.8 V vs Al$^{3+}$/Al. This is the first time that such a high voltage plateau has been reported, which exhibits high energy density and promising brilliant commercial application prospect.

The 1st, 50th and 100th charge/discharge curves at 100 mA g$^{-1}$ are shown in Fig. 2(c). It is worth mentioning that due to the low cost and durability of aluminium foil, excess anode material is used to allow full play to the cathode, so the specific capacity and scurrent density of the Al-ion battery were calculated based on the mass of the carbon paper. Even after 100 cycles, the charge and discharge curves deliver a discharge capacity of 69.92 mAh g$^{-1}$, which shows an excellent capacity performance. Considering the high voltage and large charge and discharge current density, this battery exhibits high energy and power density. The charge and discharge curves of different cycles are very similar, demonstrating a highly reversible reaction. The cycle performances of the battery under different current densities over 50 cycles are displayed in Fig. 2(d). Excellent cycle performance as well as high capacity has been achieved. At the current density of 50 mA g$^{-1}$, the discharge capacity is 84.55 mAh g$^{-1}$ over 50 cycles. Even at a high current density of 150 mA g$^{-1}$, the discharge capacity still remains 62.71 mAh g$^{-1}$ over 50 cycles. The cycle performance and coulombic efficiency of Al-ion battery at 100 mA g$^{-1}$ over 100 cycles are shown in Fig. S2 (Supplementary Information). In the initial three cycles, the charge and discharge capacity is a little unstable. While three cycles later, the capacity basically remains stable. The corresponding coulombic efficiency is steady, and after three cycles, it is almost near 100%.

After 100 cycles, the volume of the carbon paper expands dramatically compared to the original, which agrees with the analysis of HRTEM. Meanwhile, the morphology of surface still remains unchanged. The corresponding SAED images of the original and cycled carbon paper are displayed in Fig. 3(c) and 3(f), both of which are similar and demonstrate the characteristic of graphitic crystalline. From the above description, we can summarize as follows: (1) the crumpled nanosheets provide a large surface area, which is beneficial for the sufficient contact between the active material and the liquid electrolyte 18–22 (2) during charge and discharge process, the electrochemical reaction takes place only in the interlayer of graphite, and the surface of the graphite does not involve in the reaction (3) due to the good crystallization, the structure of graphite remains stable even after tens of cycles, which can improve the cycle life (4) considering the dramatically increased neighbor graphite intercalating space, the intercalated ions might involve big coordination ions, not only single Al\(^{3+}\) (small ionic radius). To research the charge and discharge process meticulously, we prepared a series of cathode produces through a charge–discharge cycle. Fig. S3 (Supplementary Information) shows HRTEM images of the products after charge(a,b) and discharge(c,d) processes. As shown in Fig. S3 (Supplementary Information), from charge process to discharge process, the distance of the adjacent graphitic layers is rising gradually from 0.3428 nm to 0.3667 nm, which is in accordance with the XRD through a charge-discharge cycle.. Fig. S4(Supplementary Information) shows the peak of the cathode moves to the left, thus, on the basis of the formula: 2dsinθ=nλ, the distance of the adjacent graphitic layers is rising, further conforming to the HRTEM images. Therefore, the adjacent graphitic layers expand after charged, which can accommodate more inserted ions.

**Fig. 3** TEM (a), HRTEM (c) and the corresponding SAED (e) images of the original carbon paper.TEM (b), HRTEM (d) and the corresponding SAED (f) images of the cycled carbon paper after 100 cycles.

Fig. 3(a) and 3(b) show the TEM images of original carbon paper and cycled one. Ultrathin crumpled nanosheets with hundreds of nanometers in diameter can be seen clearly. Despite of undergoing 100 charge and discharge cycles, nearly no difference can be observed on the surface of the carbon paper. However, if taken a close view, things are quite different, as shown in Fig. 3(c) and 3(d). The distance of the adjacent graphitic layers is about 0.33 nm, which is the characteristic of graphitic crystalline. However, after 100 cycles, the neighbor graphite intercalating space of the discharged carbon paper is greatly enlarged, that is ca. 0.455 nm. These could also be observed visually in Fig. S1d (Supplementary Information). After 100 cycles, the volume of the carbon paper expands dramatically compared to the original, which agrees with the analysis of HRTEM. Meanwhile, the morphology of surface still remains unchanged. The corresponding SAED images of the original and cycled carbon paper are displayed in Fig. 3(c) and 3(f), both of which are similar and demonstrate the characteristic of graphitic crystalline. From the above description, we can summarize as follows: (1) the crumpled nanosheets provide a large surface area, which is beneficial for the sufficient contact between the active material and the liquid electrolyte 18–22 (2) during charge and discharge process, the electrochemical reaction takes place only in the interlayer of graphite, and the surface of the graphite does not involve in the reaction (3) due to the good crystallization, the structure of graphite remains stable even after tens of cycles, which can improve the cycle life (4) considering the dramatically increased neighbor graphite intercalating space, the intercalated ions might involve big coordination ions, not only single Al\(^{3+}\) (small ionic radius). To research the charge and discharge process meticulously, we prepared a series of cathode produces through a charge–discharge cycle. Fig. S3 (Supplementary Information) shows HRTEM images of the products after charge(a,b) and discharge(c,d) processes. As shown in Fig. S3 (Supplementary Information), from charge process to discharge process, the distance of the adjacent graphitic layers is rising gradually from 0.3428 nm to 0.3667 nm, which is in accordance with the XRD through a charge-discharge cycle.. Fig. S4(Supplementary Information) shows the peak of the cathode moves to the left, thus, on the basis of the formula: 2dsinθ=nλ, the distance of the adjacent graphitic layers is rising, further conforming to the HRTEM images. Therefore, the adjacent graphitic layers expand after charged, which can accommodate more inserted ions.

**Fig. 4** XPS spectra of the original and cycled carbon paper: (a) C 1s, (b) Cl 2p and (c) Al 2p. (d) Raman spectra of the original and cycled carbon paper.

Fig. 4(a-c) show the XPS spectra of the original carbon paper and charged and discharged one in 100th cycle. The C 1s XPS peaks of the original and cycled carbon paper remain unchanged, which demonstrates that the surface of the graphite is not involved during the charge and discharge process, matching with our assumption in Fig. 1 and TEM in Fig. 3. Slightly differences can be seen in the Cl 2p XPS peaks, as shown in Fig. 4(b), However, the differences of Al 2p XPS peaks are obvious. After a charge process, a new peak appears, which can be attributed to the formation of a new kind of aluminium chloride, named AlCl\(_x\). After charged, the cathode material is washed by alcohol under ultrasonic cleaning for several times for EDS test.

EDS mapping images(Fig. S5) also provide that Al and Cl elements intercalate into the graphite layers, matching with our assumption in Fig. 1. Fig. 4(d) shows the Raman spectra of the original carbon paper and charged and discharged carbon paper in 20th cycle. Two peaks can be found at 1352 cm\(^{-1}\) (D band) and 1580 cm\(^{-1}\) (G band), respectively. The D band presents a disordered graphitic structure, whereas the G band corresponds to the crystallinity of graphite.23,24 Nearly no obvious differences can be found, which reveals that the structure of graphite before and after cycling is unchanged.

As discussed above, during charge and discharge process, different from the behavior of Li-ion battery, two single ions/coordination ions intercalate and deintercalate in the cathode, i.e., Al\(^{3+}\) and [Al\(_x\)Cl\(_y\)]. As cathode material, carbon paper (composed of graphite) does not form common chemical bonds with the intercalated ions, only providing large space (graphite layers) for the intercalation and deintercalation of ions/coordination ions. After intercalated in the graphite layers, the formed AlCl\(_x\) is stored in neighbor graphite intercalating space by van der Waals\(^{1}\) forces. As can be seen in Fig. 2(b), when discharged at 50 mA g\(^{-1}\), two discharge plateaus can be observed at 2.1-1.85 V (voltage stage I) and 1.85-1.52 V (voltage stage II), respectively, which is attributed to the simultaneous intercalation of Al\(^{3+}\) and [Al\(_x\)Cl\(_y\)]. The voltage stage I agrees well with the c peak in the CV curves (Fig. 2(b)) while the voltage stage II accords with the a and b peaks in the CV curves (due to the extraordinary adjacency of the a and b peaks, the edge of the corresponding voltage plateaus are un conspicuous and ambiguous).
Due to the big size of coordination ions and Al ions, the graphite layers are enlarged, which can be supported by the comparison of original and cycled carbon paper: (1) the volume expansion can be visually seen by experimental photographs in Fig. S1d (Supplementary Information) (2) the neighbor graphite intercalating space increases from 0.33 nm to 0.455 nm.

After tens of cycles, part of the graphite sheets crush into small pieces, and the surface of the Al foils is corroded, as shown in Fig. S2, demonstrating a highly reversible charge and discharge process. Stable with nearly 100% coulombic efficiency (Fig. 2(d) and Fig. S6 (Supplementary Information), however, the microstructure of the graphite remains unchanged. These results can be supported by TEM and XPS and Raman in Fig. 4. The unchanged graphite structure also proves that graphite does not form common chemical bonds with the intercalated ions.

It is worth noting that in the initial few cycles the discharge capacity gradually increases (Fig. 2(d)). These may be attributed to the following reasons: First, the graphite layers expand extremely during the intercalation of coordination ions, especially in the initial cycles. Then the volume adjustment occurs, which causes the graphite layers more suitable for the intercalation and deintercalation of coordination ions. Second, the simultaneously enlarged specific surface area of the cathode is in favor of the contact between the graphite and electrolyte. After several cycles, the capacity remains stable with nearly 100% coulombic efficiency (Fig. 2(d) and Fig. S2), demonstrating a highly reversible charge and discharge process.

Conclusions

In summary, a new Al-ion battery has been proposed and established. A very high and obvious voltage plateau at ca.1.8 V vs Al\textsuperscript{3+/Al} is achieved. As an Al-ion full battery, this is the first time that such a high voltage plateau has been reported. Even discharged at 100 mA g\textsuperscript{-1}, the capacity can reach as high as 69.92 mAh g\textsuperscript{-1} over 100 cycles with high reversibility. Due to the low cost and abundant raw materials (aluminium and graphite), the Al-ion battery established in this work shows bright prospect in the commercial application of Al-ion batteries. It is a creative work in the field of Al-ion battery and will greatly promote the development of potential alternatives to lithium-ion batteries for electric energy storage. The work was supported by the 111 Project (No. B13004)
