This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Reactions of the methylsulfinyl radical [CH₃(O)S⁺] with oxygen (³O₂) in solid argon

Hans Peter Reisenauer, *a* Jaroslaw Romanski, *b* Grzegorz Młoston,*b* Peter R. Schreiner*a

Received (in XXX, XXX) Xth XXXXXXXXXX 20XX, Accepted Xth XXXXXXXXXX 20XX

DOI: 10.1039/c0xx00000x

The atmospherically highly relevant methylsulfinyl radical (CH₃(O)S⁺) readily reacts with molecular triplet oxygen in cryogenic argon matrices containing small amounts of ³O₂. Comparison of experimental and computed IR- and UV/Vis spectra, including isotope exchange, show that the initially formed ³O₂ adduct has the structure of a peroxy radical (CH₃(O)SOO⁺), which upon irradiation with UV light isomerizes to the methylsulfonyl radical (CH₃SO₂⁺). The latter transforms into the methanesulfonic acid radical (∙CH₃SOOH) by irradiation with visible light. During the matrix photolysis small amounts of SO₃ and methyl radical were detected indicating competitive direct photodissociation.

Volatile sulfur compounds such as hydrogen sulfide and dimethylsulfide (Me₂S, DMS) produced from natural plankton are emitted to the atmosphere and are converted into a plethora of sulfur products via radical processes. As a part of the so-called ‘sulfur cycle’ they are of great importance for the atmospheric sulfur balance and DMS as the major component of biogenic emissions. The impact of sulfur compounds on the climate is explained based on the ‘CLAW’ hypothesis. DMS and other volatile sulfur compounds undergo cascade conversions in the atmosphere eventually leading to sulfuric acid and methanesulfonic acid (Scheme 1). Methylsulfinyl radical (1) and methylsulfonyl radical (2) are recognized as important intermediates involved in these processes.

A recent study reports the high vacuum flash pyrolysis (HVFP) of allylmethylsulfoxide (3) generating the highly stabilized π-radical 1 isolated in an Ar matrix at 10 K. Similarly, 2 was trapped starting with allylmethylsulfone (4) (Scheme 2).

![Scheme 2 Generation of 1 and 2 starting with allylmethylsulf oxide (3) and allylmethylsulfone (4), respectively](image)

The study showed that 2 in comparison with 1 is significantly less stable and easily undergoes partial decomposition in the gas phase leading to the formation of SO₃ and methyl radical. To date little is known about the reactions of 1 and there are only a few kinetic studies of its reactions with O₂, O₃, and NO₂. In the case of the reaction with ³O₂, the formation of an adduct with the structure of the methylsulfinylperoxyl radical (5) as the key intermediate was postulated. However, to the best of our knowledge, no spectroscopic data for 5 have been presented to date.

![Scheme 3 Most relevant [CH₃SO+] radical species (5-8)](image)

The fundamental question whether the formation of 5 by addition of 1 to molecular oxygen is an exo- or an endothermic process has not yet been unambiguously answered by theory. The ΔH° values computed at ab initio and density functional theory (DFT) levels with large basis sets vary considerably; G2(MP2) computations indicate slightly exothermic (~2.5 kcal mol⁻¹) formation of 5.

The main goal of the present work was to determine if this reaction takes place at all and to examine the structure of the product formed. Equally important for the understanding of atmospheric chemistry is an investigation of the photochemistry of the initially formed oxygen adduct. The matrix isolation technique currently is the best method to provide reliable answers to both questions.

![Scheme 4 Generation of methylsulfinyl radical (1) by HVFP of precursor 3 and its reaction with oxygen in solid argon at 10 K](image)

Following the previously described protocol for the generation of 1, a sample of the precursor 3 was pyrolized at 600 °C and the stream of products was co-condensed at 10 K with a large excess of argon containing ca. 0.5, 1.0 or 5.0 vol% of oxygen, respectively (Scheme 4). In experiments with 0.5 and 1.0 vol% of ³O₂ only partial conversion of 1 and allyl radical (9) was observed. In the IR spectra the characteristic absorptions located at 800 cm⁻¹ (for 6) and at 1068 cm⁻¹ (for 1) were still present. In addition a new, intense band found at 1191 cm⁻¹ provided evidence for the formation of a new product. However, in the case of experiments performed with 5 vol% ³O₂ content, the conversions were com-

plete and none of the bands of 1 or 9 were found in the pyrolysate. Two new sets of characteristic absorptions indicate the formation of two new products. Based on previously reported data\(^\text{10}\) and on the basis of results of our present studies on the reaction of the allyl radical generated by HVFP of 1,5-hexadiene with molecular oxygen, one of them was readily identified as the allyldioxyl radical (10) (Fig. 1). Another new product with an intense band located at 1191.1 cm\(^{-1}\) and less intense at 1295.5 and 686.3 cm\(^{-1}\), respectively, was identified as 5. Conceivable alternative structures resulting from bonding to the O-atom do not represent energy minima (ESI, Fig. S1).

Fig. 1 FTIR spectra of pyrolysis of precursor 2 (A) and 1,5-hexadiene (*) (B) isolated in an Ar matrix containing 5.0 vol% O\(_2\); pyrolysis products of 2 isolated in an Ar matrix in the absence of O\(_2\) (C)

The UV/Vis spectrum of the matrix material showed a broad absorption maximum at \(\lambda_{\text{max}}\) = 394 nm (Fig. 2, full line). Based on this observation, photolyses (Hg high pressure lamp, monochromator, \(\Delta\lambda = 10\) nm) were carried out with light at \(\lambda = 366\) nm or alternatively at \(\lambda = 405\) nm. In both cases, disappearance of the initial IR- and UV/Vis absorption bands attributed to 5 was observed, whereas those of 10 remained unchanged. The products formed thereby were identified as SO\(_3\) and 6. The presence of small amounts of SO\(_3\) is evident from its characteristic IR bands at 1391/1383 cm\(^{-1}\), 527/521 cm\(^{-1}\), and 489 cm\(^{-1}\).\(^\text{11}\) The fate of the methyl radical as the co-product of the photodissociation reaction remains unclear. Neither its IR bands nor those of the methyl peroxy radical\(^\text{12}\) as the expected reaction product with excess O\(_2\) could be found, most probably because their specific intensities are much lower than that of SO\(_3\). The structure of the second product was deduced on the basis of its UV/Vis spectrum revealing a very strong absorption band in the range of 510–350 nm with a distinct vibrational fine structure along with a much weaker broad structureless absorption between ca. 700 nm and 530 nm (Fig. 2, dashed line). Similar bands were reported in a laser flash photolysis experiment for the initial photodissociation product of bis(methylsulfonyl)peroxide and assigned to 6.\(^\text{13}\) Moreover, similar bands were observed for the product obtained from the same precursor after HVFP with subsequent isolation in noble gas matrices.\(^\text{14}\)

In good accordance with the experimental UV/Vis spectra, TD-UB3LYP computations of the excitation energies (ESI, Table S3) provide two weak absorption bands at 388 and 366 nm for 5 and a very intense band at 476 nm for 6, whereas the photochemical final product 7 should have no absorption above 315 nm. For the unobserved isomer 8 the computations predict absorptions of medium intensity at 375 and 361 nm that are close to those of 5. It might well be that 8 forms upon irradiation, but is photolabile and therefore its concentration stays below the detection limit.

Fig. 2 UV/Vis spectra of pyrolysis of precursor 2 isolated in an Ar matrix containing 5.0 vol% O\(_2\)

The most intense IR bands attributed to 6 were observed at 757, 1334, and 1441 cm\(^{-1}\) (Fig. 3, negative bands). They coincide well with those reported for argon matrix isolated 6.\(^\text{14}\) Comparison of the experimental IR bands with computed IR spectra of 6 was not helpful in supporting the structural assignment. Especially the theoretically predicted strong band for the symmetric SO\(_3\) stretching vibrations (\(v_1\)) has no counterpart in the experimental spectrum. Due to the special electronic situation of \(C_3v\) symmetric 6 with a degenerate singly occupied highest molecular orbital that is subject to Jahn-Teller distortion to \(C_2\) symmetry, one may expect strong vibronic coupling of the energy levels and anharmonic potentials. The electronic situation of 6 is similar to that of the highly symmetric NO\(_3\) radical for which it was shown that standard DFT and \textit{ab initio} methods completely fail in predicting the vibrational frequencies due to vibronic coupling and highly anharmonic potentials.\(^\text{15}\)

Prolonged irradiation of the matrix with light at \(\lambda = 435\) nm showed the disappearance of 6, and no absorption maximum could be found in the UV/Vis spectrum above 300 nm. The IR spectra of the new product can be assigned to C-centered radical 7. The absorption band located at 3569 cm\(^{-1}\) unambiguously proves the formation of the –SO\(_2\)OH group. This position is very close to OH-stretching vibration of argon matrix isolated H\(_2\)SO\(_4\) at 3567 cm\(^{-1}\) and CH\(_2\)SO\(_2\)H at 3579 cm\(^{-1}\), respectively.\(^\text{16}\) In addition, absorptions at 1403, 1391, 1383, 1189, 1184, 842, 827, 784 cm\(^{-1}\), partially split by matrix effects, can also be attributed to 7 (ESI, Fig. S3). Upon labelling two of the three oxygen atoms of 7 by \(^{18}\)O, two distinct OH stretching bands at 3570.0 and 3559.0 cm\(^{-1}\) with an intensity ratio of 1:2 were

Page 2 of 3
observed (ESI, Fig. S4) as expected for the postulated structure. Apparently, thermodynamically most stable isomeric radical 8

does not form in the matrix under photolysis. Neither 8 nor the expected decomposition products such as methoxy radical and

SO₂ could be detected.

Structure 5 is expected to exist as a mixture of rotamers by rotation around the S–O single bond. The results of DFT and ab
initio computations show that they differ by 0.5 kcal mol⁻¹ (see data for 5 in ESI). The computed IR spectrum of equal amounts

of two representative rotamers fits well to the experimental spectrum (Fig. 3). The most intense band observed at 1191 cm⁻¹ is
attributed to the S=O double bond stretch. Apparently, within the applied experimental spectral resolution the positions of the ν(S=O) absorption bands are identical for both rotamers.

![Fig. 4](image_url)

**Fig. 4** Isotopical band shifts of the [¹⁸O₂]-methylsulfinyldioxy radical (¹⁸O₂-5); radicals 5 were obtained by reaction of methylsulfinyl radical (1) with triplet ¹⁸O₂ (A) and triplet ¹⁴O₂ (B).

The formation of 5 as the initial product in the reaction of 1 with ¹⁸O₂ is strongly supported by additional isotopic labelling

experiments. In particular, the observed spectral shifts in the IR spectrum of the ¹⁸O-labelled product were key for the spectral

assignments (Fig. 4; in ESI, Table S1and S2). The most intense IR band of 5 displayed only a very small isotopic band shift (+0.2 cm⁻¹) when triplet ¹⁸O₂ was used instead of triplet ¹⁴O₂. This IR band could be attributed unambiguously to a pure S=O stretching vibration. Furthermore, the labelling experiment provides evidence that the pair of weak bands at 1100 and 1082 cm⁻¹ has to be assigned to the O=O stretching vibrations of two rotamers of 5. The experimental band shifts of –61.0 and –58.0 correspond well to the isotopic shifts (ESI, Table S1 and S2). Moreover, the expected band shifts were also observed for the S–O stretching vibration (600 cm⁻¹ and 555 cm⁻¹ versus 575 cm⁻¹ and 534 cm⁻¹, respectively). The observed IR band shifts after deuteration of the methyl group (ESI, Fig. S5) also agree very well with these band assignments. Whereas, in accordance with DFT computation (ESI, Fig. S6), the positions of the ν(S=O) and the ν(O=O) remain almost unchanged, large bathochromic shifts were observed for the δ(CH₃) and ρ(CH₂)

vibrations. The present study shows that atmospherically highly relevant radical 1 generated in the gas phase by high-vacuum flash pyrolysis reacts spontaneously with molecular oxygen in a solid argon matrix under cryogenic conditions. Obviously, the formation of the oxygen adduct is a nearly barrierless, exothermic process. The structure of initially formed peroxy radical 5 was proven by comparison of computed with experimental IR and UV spectra as well as through extensive isotopic labelling experiments. Upon irradiation with near UV light, adduct 5

undergoes photochemical dissociation into SO₂ and a methyl radical or isomerizes to 6. The latter is also not stable against irradiation with visible light and eventually transforms to 7. These results underscore earlier postulates regarding the existence of a reactive oxygen adduct of the methylsulfinyl radical. Furthermore, our results demonstrate the importance of photochemical transformations in atmospheric oxidation processes of volatile organic sulfur compounds. These photochemical pathways have not yet been considered in the discussions related to the atmospheric sulfur cycle.
