Accepted Manuscript

This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about *Accepted Manuscripts* in the **Information for Authors**.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard <u>Terms & Conditions</u> and the <u>Ethical guidelines</u> still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

www.rsc.org/

Polymerization of 1,4-diaminonaphthalene on various Cu substrates resulting in stereoselectively well-defined metalorganic coordination polymers is reported. By using different crystallographic planes (111), (110) and (100) of a Cu substrate the structure of the resulting coordination polymer was controlled.

On surface polymerization has recently been used as an efficient method for the preparation of well defined, novel types of polymers directly at a surface. Many contributions in this area deal with on-surface covalent carbon-carbon or carbon-nitrogen bond formation. In addition, this approach has also been successfully applied to the formation of metal-organic polymers containing carbon-metal² or nitrogen-metal coordination bonds.³ In the latter cases, a metal atom is either added to or extracted from the surface during polymerization. It is well known that the surface is not static (especially above room temperature) and some of the metal atoms can be readily pulled out from the surface and be ligated by the organic adsorbate. 4 Metal-organic coordination polymers are highly interesting because they show unique properties. Considering structural properties, either 3D or 2D coordination frameworks can be constructed at the surface. Moreover, such surface adsorbed coordination networks reveal interesting catalytic,⁵ magnetic⁶ and electric⁷ properties. It is obvious, that all these properties are influenced and controlled by the structure and geometry of the coordination polymer. Another aspect is that the electronic configuration of the coordination center (metal atom) in such networks is not readily predictable. The metal can have different oxidation states and charges because the surface is working as an electron reservoir which can interact with the organometacomplex at the surface.⁸ In specific cases the electronic configuration of the complex at the surface is different as compared to its electronic state in solution and in solid state. For example, Cu adatom on a Cu (111) substrate can be negatively charged where it is bonded to a cyano group. 4d It is obvious that complexe interacting with a substrate might show different catalytic activit Therefore, understanding the geometry of coordination systems at a surface within the 2D network and also its interaction with the substrate is of great importance for future application of these systems, for example in catalysis. Here, we report the effect of the substrate reconstitution on the final geometry of the coordination network and show that different crystallographic structures of same metal (in this case Cu) control the stereochemistry of the polymerization leading to coordination polymers with differe of relative configurations.

Polymerization of 1,4-diaminonaphthalene at Cu (111) Evaporation of 1,4-diaminonaphthalene (DAN) at the Cu (112) substrate at room temperature leads to formation of monolayers where the organic molecules are randomly distributed showing different orientations on surface. The random orientation of DAI's indicates that the interaction between the organic molecules s weaker than the one between DANs and the Cu-substrate. After heating of the sample to 390K most of the molecules just desorbe a but we also observed the formation of some dimers which we found to be very mobile at the surface under the applicaconditions. These dimers and remaining monomers, upon further heating of the surface to 400K started to form longer oligomer. This process was slow and not very efficient due to kw concentration of monomers and dimers caused by the competing thermal desorption. Better results were obtained by depositing DANs directly at a hot Cu (111) surface. This process allowed the desorbed diaminonaphthalenes to be continuously recharged to th surface which can diffuse and react with oligomers leading to further growth of the polymers (fig. 1a). By using this set ur oligomers with a chain length of up to 20 nm were formed. It clearly visible from the STM images that most polymers grew alor one of the three main crystallographic axis of the substrate. The Co

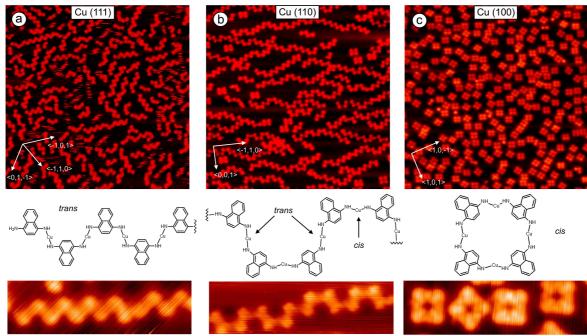

Figure 1. Polymers formed after deposition of DAN at a hot Cu (111) substrate (a) 45 x 45 nm2, Cu (110) substrate (b) 45 x 45 nm2 and Cu (100) substrate (c) 45 x 45 nm2. STN pictures a-c: -2 V, 10 pA. Below proposed chemical structures of the dominant polymers fractions for each substrate and zoom in of the corresponding single chains.

N bond in the Cu-complex was found to be very stable. The amino ligands are trans-oriented to each other as a naphthyl-NH-Cu-NHnaphthyl complex. Note that dehydrogenation in amines is known to occur at Cu (111) and at Au (111) substrate. Importantly, while in solution bisamino-Cu bonds can rotate around the Cu-N-bond, due to van-der-Waals interactions with the substrate free rotation is suppressed at the Cu surface. Therefore, Cu-amino complexes can be formed as different stereoisomers at Cu. Guided by the cis/trans-nomenclature to describe alkene geometry, we herein also use the trans and cis terminology to specify the surface adsorbed biasamino-Cu-complexes. In the trans-isomer, the protons of the amino ligands are trans-oriented to each other whereas in the cis-complex the protons of the amino ligands are oriented in cis configuration to each other. As the major oligomeric structure formed on a hot Cu (111) surface we found an all transconfigured coordination polymer revealing that oligmerization occurred with high trans-selectivity. The stability of the coordination polymers is remarkably high. Chains could be mechanically manipulated by the STM tip without losing their shape (fig. 2a-c). The interaction of a Cu built-in atom of the oligomer with the N atom is much stronger than that with metal substrate. For example, an oligomer containing 7 Cu atoms was readily manipulated by pushing from one edge without destroying the polymeric structure. This means that the weakest bond in the system (likely the Cu-N bond) is much stronger than the interaction of the all oligomer with its 7 Cu atoms with the substrate. A strong interaction within the oligomers and weak interaction of the oligomer with the substrate gives also the possibility to elastically bend the coordination bonds (fig. 2b). It was interesting, that after manipulation the oligomer returned to its original lowest energy structure revealing shape memory behavior (fig. Polymerization of 1,4-diaminonaphthalene at Cu (110). When DAN molecules were deposited on Cu (110) at room temperature vacuum they form well-ordered structures where the organ molecules interact via hydrogen bonding. Heating of the substrati to 420K leads to desorption of most DANs, but some of ther formed short oligomers. As for the Cu (111) case discussed above better results were achieved when the organic molecules wer directly deposited on a hot Cu (110) surface. Polymer chains we formed, but interestingly, the shape of most oligomers differal significantly from the shape obtained for DAN-polymerization at C (111) where most of the polymers were generated with transconfiguration leading to a zig-zag type shape of the chain. Howe -r. at Cu (110) the largest part of the monomers is connected with alternating trans-cis-trans-cis relative configuration providing a Ushape type structure (fig. 1b). One can clearly identify a min fraction which polymerized with trans-configuration leading to zig-zag-type oligomer.

Polymerization of 1,4-diaminonaphthalene at Cu (100). DAN monomers were deposited at room temperature at Cu (10th providing a submonolayer with random distribution of the molecules. DAN did not form ordered or well packed islands Differences in self-assembled monolayers between Cu (111), (1 (110) and Cu (100) are caused by different periodicity and symmetry of these surfaces. Heating of the substrate containing physisorbed DAN molecules to 390K provided tetramers v. "h rectangular shape at high yield (fig. 1c). The build-up of cyclic tetramers is a result of a highly diastereoselective all-cis-amino-C complex formation. The suggested chemical structure is shown below. For comparison with the Cu (111) and Cu (110) cases we also deposited DANs directly at a hot Cu (100) surface. For this substra the hot and cold deposition procedures afforded similar results. Only a small amount of the molecules was desorbed during heating likely due to faster reaction and also due to stronger interaction or

the monomer with the Cu substrate. To a small extent, the formation of cyclic tetramers was also observed at previous Cu (110) substrate (fig. 1b). To get a better picture on the selectivity of DAN oligomerization as a function of the substrate, we analyzed the number of trans and cis configured naphthylNH-Cu-NHnapthyl complexes extracted from various STM pictures which allowed us to gain statistical information on the trans/cis-selectivity as a function of the Cu substrate. On Cu (111) surface trans-configured bisamino-Cu-complexes occurred with 85% abundance A near complete cisselectivity was observed for Cu (100) where almost all complexes (99%) were formed as cis-isomers. Cu (110) results in an intermediate state with the trans to cis complexes in a 66% to 34% ratio.

Theoretical investigations. Based on STM data we proposed possible configurations of the various Cu-DAN-oligomers (fig. 3), which were in good agreement with the experimentally observed structures. In the all-trans-configured oligomer identified as a zig/zag-shaped system on Cu (111), the Cu-adatoms are lined up with a calculated distance of 0,75 nm which is in very good agreement with the experimentally determined value (0,75 nm). Metal atom chains are parallel to the three main symmetry axes (<0,1,-1>, <-101>, and <-110>) of the Cu (111) substrate which forms of polymer mostly parallel to this three directions (see main chains on fig. 1c). This also fit in to theoretical model because structure can be easy rotated by 60° to get this same adsorption geometry. For the Cu (110) substrate the experimentally observed U-shape oligomer occurred with some zig/zag shape oligomer similar to previous structure. In this case, the Cu-adatoms appear highly regular in 0,79 nm distance from each other and form a zig/zag relative arrangement. In some cases all metal adatoms can lie in line along <3,3,2> axes or its mirror direction <3,3,-2> marked by red arrows (fig. 4). When all Cu adatoms are parallel to this axes then it effects only trans substitution of the DAN molecules. When adsorption of the adatoms is not linear and it changes between this axes (dotted arrow) then it causes substitution of next DAN molecule in cis configuration. This substitution and growth mechanism are random which is clearly visible at large area (fig. 1b) and it fits well to the proposed model. Cis substitution can only occur parallel to the <-1,1,0> direction when two DAN molecules

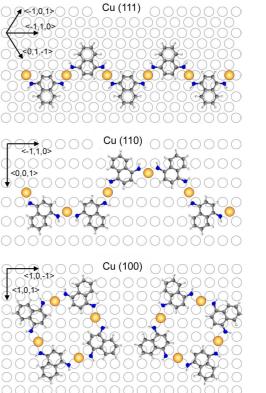

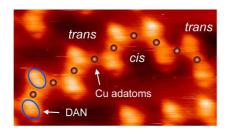

Figure 3. Adsorption geometry of DAN-Cu polymer at different Cu substrate

are mirrored in <0,0,1> axes. Interestingly, whereas for the tran configuration the Cu-adatom lies in line in the middle of the two Natoms of the amino ligand (angle N-Cu-N = 180°), in the ciconfigured complex the N-Cu-N angle is smaller (120°). This bending of the complex leads to an oligomeric structure where all distances between the Cu-adatoms are very similar (theory: 0,79 nm, experiment: 0,81 nm) with main trans-cis-trans-cis alternation configurations. A smaller angle (150°) was also observed for the ciscomplexes on Cu (100) where also theory predicts the rectangular tetrameric structures. In this case there are two theoretical configurations on the surface which are their mirror reflection (mirror plane is parallel to one of the symmetry axes of the substrate <1,0,-1> or <1,0,1>). Counting both of these configurations on several pictures gives 50:50 ratio and informatic 1 that energy of adsorption and geometry at the substrate is exa t the same which is in very good agreement with the proposed structure. Also the distance between Cu adatoms is in good agreement with theoretical model (theory: 0,85 nm, experiment. 0,9 nm). Comparing optimal temperatures for the reaction ve discovered that reaction can easily occur at Cu (111) and Cu (100) substrate (390-400 K). Creation of the polymers at Cu (110) surface need 20K higher temperature. Probably it is caused by high r stability of Cu atom in subsurface region and higher energy of is diffusion which is necessary to create longer polymer chains.

In summary we observed that different crystallographic planes this same substrate [Cu (111), Cu (110) and Cu (100)] can influence for the nature of polymers. Growing of the polymer at Cu (11) substrate provides mostly to trans conformation while Cu (

gives only cis conformation. Cu (110) have both of these properties and trans and cis conformation can exist on the surface with random distribution or also regular trans-cis-trans-cis order. This strong selectivity of the crystallographic plane of Cu- surface orientations with respect to the final product structures can be helpful to optimize catalytic processes and isomerization at surfaces. We also showed by manipulation of the polymer chains that coordination bonded systems N-Cu-N are very stable when metal atoms are extracted from the surface while the interaction of them with the metal substrate is weak (compared to the interaction in polymer chain).

In summary we observed that different crystallographic planes of this same substrate [Cu (111), Cu (110) and Cu (100)] can influence for the nature of polymers.
