This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Insight into the esterase like activity demonstrated by an imidazole appended self-assembling hydrogelator.

Nishant Singh, Maria P. Conte, R. V. Ulijn, Juan F. Miravitlles and Beatriz Escudero*

A low molecular weight hydrogelator with covalently appended imidazole moiety is reported. Capable of percolating water in the pH range of 6 to 8, it proves to be an efficient catalyst upon self-assembly, showing Michaelis-Menten type kinetics. Activities at different pH correlated to dramatic structural changes observed. It can hydrolyse p-nitrophenyl acetate (pNPA) as well as inactivated esters, L and D-phenylalanine methyl esters. The enhanced activity can be related to the conglomeration of catalytic groups upon aggregation resulting in their close proximity and the formation of hydrophobic pockets.

Mimicking and emulating enzymes by means of synthetic catalysts is currently an area of huge interest. Tertiary structure allows various functional groups to be precisely arranged in three-dimensional space, creating sites to bind substrates and positioning chemical functional groups to enable catalysis. Prediction and synthesis of enzyme performance from de novo designed primary sequence able to fold and function accordingly is currently not possible. However it is possible to attain enzyme like activity by using smaller self-assembling molecules or peptides owing to the ordered arrangement of the catalytically active sites/functional groups. Several groups have demonstrated esterase-like activity using metal based nanoparticles, micelles or dendrimers with large molecular weights and mostly with spherical symmetry. Histidine-containing peptide nanofibrillar systems have been reported recently as catalysts for activated ester hydrolysis (2,4-dinitrophenyl acetate and p-nitrophenyl acetate) and have revealed the role of the fibrillar nanostructure and multivalency on the catalytic performance. In this communication we report low molecular weight hydrogelator (1) with covalently linked imidazole moieties demonstrating esterase like activity. The ordered arrangement of the catalytic centres upon self-assembly of molecules into a fibrillar network is taken advantage of to attain improved catalytic activity when compared to the non-aggregating analogue. In contrast to previously reported examples, 1 is a small synthetically simple compound that is able to hydrolyse not only activated but also non-activated aminoacyl esters.

Scheme 1: Self-aggregating compound 1 and non-aggregating analogue 2.

Compound 1 with a minimum gel concentration of 5.7 mM was tested for the esterase like activity using pNPA as substrate. pNPA upon hydrolysis yields chromogenic p-nitrophenolate anion which can be monitored at 400nm using UV spectroscopy (see ESI for details). The initial parts of the kinetic curves for hydrolysis at different concentrations of substrate were fitted to Michaelis-Menten equation for respective pH values. The obtained $K_M$, $k_{cat}$ and $V_{max}$ values are presented in Table 1.
The calculated pKa values for aggregated compound 1 are 5.9 and 6.6, with monoprotonated species in abundance in this range (see Fig. S1). This drop in pKa value to 5.9 is only observed for the aggregated form of 1, as in solution the pKa values are similar (6.2 and 6.3). This indicates the increase in basicity of one of the two imidazole moieties in molecule 1 only in the self-assembled state.

The catalytic efficiency ($k_{cat}/K_m$) for imidazole molecules in solution is known to drop significantly at lower pH values.\textsuperscript{2a,3,4a} The higher amount of protonated imidazole moieties are held responsible for this which normally are not catalytically active. To our surprise for the pH 6 and 6.5 we don’t observe this drop, infact a slight rise in the catalytic efficiency when compared to higher pH values like 7 and 7.5. This unusual catalytic efficiency around the pKa values of selfH-assembling 7.5. This unusual catalytic efficiency when compared to higher pH values like 7 and 6 and 6.5, cannot simply be attributed to the contribution of the fraction of deprotonated imidazole. Instead, cooperativity between both protonated and deprotonated imidazole groups is likely responsible.

The solubility ($K_{sol}$) of compound 1 was obtained by NMR experiments for pH 6, pH 7 and pH 8 are 2.85 mM, 1.95 mM and 0.95 mM respectively (Fig. S4). The $K_{sol}$ (second order rate constant) values observed at these pH respective non aggregating concentrations of compound 1, were significantly lower than at the self-assembling concentration (Fig. S3). Thus, highlighting the fact that observed catalysis is not by the molecules in solution but due to the catalytically active fibers. This was further confirmed by the catalytic activity observed for the non-assembling analogue 2. The $K_{sol}$ for 2 at pH 6.5, pH 7 and pH 8 are 0.5 M$^{-1}$s$^{-1}$, 0.7 M$^{-1}$s$^{-1}$ and 2.2 M$^{-1}$s$^{-1}$ which are significantly lower than for 1 under identical conditions. The obtained linear relationship between velocity of product formation and substrate concentration reflected lack of any binding events unlike 1 (Fig. 1a and S2b).

Table 1: Obtained $K_{sol}$, $K_g$ and $V_{max}$ values of hydrolysis of pNPA by 1.
1.2×10^4 M^{-1}hr^{-1} and 1.7×10^3 M^{-1}hr^{-1} respectively. The K_{sec} (2.5×10^{-4} \text{ M}^{-1}hr^{-1}) for 2 is an order of magnitude smaller than for 1 exemplifying the aggregation effect, even though there doesn’t seem to be any stereoselectivity shown by 1 (Fig. 4b). Thus, the hydrolysis of non-activated ester at the physiological pH, which to our knowledge has not been demonstrated before, reflects the fact that aggregation can lead to new emergent catalytic abilities even in small molecules owing to the high local concentration of the catalytic sites.

![Fig. 2: TEM images of gels at (a) pH 6 (scale bar: 50nm) (b) pH 6.5 (scale bar: 100nm (Inset: zoomed image of twisted fibre) (c) pH 7 (scale bar: 0.5µm) (d) pH 8 (scale bar: 0.5µm)](image)

A series of experiments were performed to obtain the structure activity relationship. The nanoscale structures of the self-assembled networks of gels as observed by TEM differ depending on pH values (Fig. 2). TEM images reveal helical fibres of 15-20 nm width at pH 6 and 6.5. The higher V_{max} values for pNPA hydrolysis obtained at these pH values can be attributed to the observed high aspect ratio fibres, allowing higher extent of substrate binding thus releasing more product. At pH 7 and 8 the molecules aggregate in flat belt-like structures which are 0.5µm wide and several micrometres long, with lower aspect ratio. The variation in morphologies based on pH can be attributed to the change in number of protonated imidazole residues. The repulsion between higher number of protonated imidazole present at pH 6 and 6.5 may result in stacking of molecules with higher slip angle between them; this gives rise to the twists observed in the nanofibers. This is not seen further away from the pK_{a} by increasing the pH due to the significantly lower number of protonated imidazole residues.

The amide I´ band in the 1630-1638 cm^{-1} region of IR for different pH values denote the presence of β-sheet like structures, which is also evident from the circular dichroism (CD) contours (Fig. 3(a) and S9). While moving from pH 8 to pH 6 an increase in ellipticity together with an apparent red-shift is observed in the CD spectra. 

![Fig. 3: (a) CD spectra obtained for gels at different pH values and (b) fluorescence emission of ANS in gels and background at different pH values.](image)

These kinds of spectral shifts to longer wavelengths are reported for twisted fibers having π-π* transitions with larger dipole moments which is expected to be the case in the protonated imidazole more than the deprotonated ones. This information obtained from CD and IR are in agreement with the TEM images of the catalytic gels which switch from twisted helical fibers (pH 6 and 6.5) to flat belt like structures (pH 7 and 8).

In order to evaluate the presence of hydrophobic binding pockets, we probed the gels at different pH values with 1-anilinonaphthalene-8-sulphonate(ANS), used extensively for this purpose in protein structure studies. When ANS was introduced in hydrogel 1, an apparent blue shift along with the rise in fluorescence was observed confirming the presence of hydrophobic pockets (Fig. 3(b)). These hydrophobic binding pockets could be formed by the central alkyl chain as well as by the L-valine isopropyl residues in 1. The molecular rigidity introduced by the two amide groups could be balanced by the flexibility of the alkyl spacer as well as the rotational freedom of the imidazole end fragments. Overall, a dynamic binding pocket could be confirmed in the vicinity of the catalytic fragment. It is also remarkable the effect of the L-valine residue as compound 2 lacking this amino acid fragment does not even aggregate under similar conditions. Moreover, the fluorescence intensity at pH 6 and 6.5 is higher and more blue shifted (472 nm for
pH 6 and 474 nm for pH 6.5) than for the rest of the pH values, suggesting stronger binding of the ANS and supporting the lower K_M values obtained for the pNPA hydrolysis at these pH values. In summary, the k_cat observed for pNPA hydrolysis shows little variation with pH, with the change in catalytic efficiency probably due to differences in substrate binding. Although the errors in K_M are significant, a clear trend is observed. This behaviour can be attributed to the difference in availability of binding pockets for each morphology. It is remarkable that a simple low molecular weight self-assembling compound bearing a minimal peptidic fragment is able to catalyse the hydrolysis of an activated ester as efficiently or even better than the few previously reported examples of longer self-assembled peptides. For instance, Stupp et al. reported a rate constant of 1.67 x 10^{-2} s^{-1} and a K_M of 0.4 mM for a bis-histidine containing decapeptide and a less efficient tetradecapeptide containing one histidine residue was described by Liang et al. (k_cat 0.19 x 10^{-2} s^{-1} and K_M 21.68 mM). The same group reported a shorter analogue (Fmoc-FH2-CONH2) with lower reaction rate than in the case of compound 1 (k_cat 0.14 x 10^{-2} s^{-1}) but with a stronger binding ability (K_M 0.76 mM). Related results have been also reported by Korendovych et al. for amyloidogenic heptapeptides bearing H residues that after self-assembly are able to coordinate Zn^{2+} and efficiently catalyse the hydrolysis of pNPA. This example however follows a different catalytic mechanism based on metal ion Lewis-acid catalysis. All these examples highlight the undoubtable link between self-assembly and emergence of catalysis which is also exemplified by compound 1.

Conclusions

In summary, we have reported an example of a catalytic supramolecular hydrogel in which binding and catalysis take place in reaction sites self-constructed solely with non-covalent interactions. We have been able to identify the probable structure-activity relationship between the different self-assembled structures and the subsequent catalytic performances of the gels. The results indicated that the presence of hydrophobic pockets, higher aspect ratio of fibres and the balance between the protonated and deprotonated imidazole can be the key factors for improved hydrolysis efficiency compared to related non-aggregating catalysts. It is remarkable the fact that enzyme-like catalytic behaviour emerges after self-assembly of small and simple molecular components. It is worth to mention that very simple low-molecular weight compounds can approach, although modestly by now, what evolution has achieved after millions of years. In fact, it has been proposed that short self-assembled peptides could have played a relevant role in the early stages of the origin of life. In this context, self-assembled catalytic peptides could have been potential precursors of enzymes.
