This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Enantioselective femtosecond laser photoionization spectrometry of limonene using photoelectron circular dichroism

Mohammad M. Rafiee Fanood, Maurice H.M. Janssen and Ivan Powis

Received (in XXX, XXX) Xth XXXXXXXXX 20XX, Accepted Xth XXXXXXXXX 20XX
DOI: 10.1039/h00000xx

Limonene is ionized by circularly polarized 420 nm femtosecond laser pulses. Ion mass and photoelectron energy spectra identify the dominant (2+1) multiphoton ionization mechanism, aided by TDDFT calculations of the Rydberg excitations. Photoelectron circular dichroism measurements on pure enantiomers reveal a chiral asymmetry of ±4 %

Terpenes are one of the most important and abundant classes of natural products. The occurrence of chiral terpenes is known to show enantiomeric variation between species, but recent studies have revealed enantiomeric variations in biogenic emissions within a single species,1, 2 and these differences may be linked, for example, to stress conditions experienced by the plant.3 Monitoring enantiomer variations may thus provide key indicators of the responses of crops, forests, and even the marine ecosystem,4 to environmental stresses such as climate change. Limonene (C10H16 – see Fig. 1 inset) is a frequently encountered exemplar of the chiral monoterpenes. Like many other terpenoids, its enantiomers are perceived to have different odours (R(+)-limonene: citrus fruit; S(-)-limonene: pine/turpentine), and in the biosphere such enantiomeric variations may be significant in signalling to populations of predators and/or pollinators. The R(+)- enantiomer (d-limonene) finds widespread domestic uses as an odorant in food, cosmetics, and cleaning products. As a common component of biogenic volatile organic compound emissions (BVOCs), it can be expected to play a significant role in certain atmospheric processes. There is, therefore, an interest in understanding the UV photochemistry and photophysics of gaseous limonene.

In this context it is interesting to consider the potential of two more recently introduced methods for enantioselective detection and probing, both based upon laser photoionization. Loge and Boesl3 have reported the resonant two photon ionization yield of S-limonene at 213 nm laser wavelength (equivalent photon energy of 5.82 eV). This excitation lies in the red foot of the limonene absorption spectrum and the circular dichroism (CD) detected in the parent ion yield has a similar asymmetry factor (~1.6×10⁻³) to that seen in the absorption CD at the same wavelength.6 In the present work we wish to evaluate the potential of an alternative new technique, photoelectron circular dichroism (PECD) using resonant ionization with an ultrafast laser.7 PECD detects a forward-backward asymmetry in the photoelectron angular distribution relative to the photon beam propagation direction with asymmetry factors that range, for single photon ionization in the VUV and SXR regions, from 10⁻³ — 0.4.8,9 Very recently it has been shown that similar asymmetries can be seen using 400 nm fs laser pulses to ionize various bicyclic monoterpenoids10 or methyl oxirane,14 although very different behaviour in the higher odd Legendre moments – uniquely accessed by the multiphoton excitation – were apparent. Here we seek further insight with a different molecular system.

The experiment uses a single detector spectrometer having velocity map imaging charged particle optics for both electron and ion detection.15 The position sensitive delay line detector 16 is capable of measuring the full 3D electron momentum from the time and position of arrival of individual electrons. Alternatively, by reversal of the apparatus extraction and detector potentials the time-of-flight of ions can be measured on the same detector. Because of the much longer flight times of the ions these voltages can be rapidly switched to ion mode immediately after electron detection, allowing the delayed coincidence between an electron and ion pair from a single molecular ionization event to be detected. Electrons can then be mass-tagged according to the identity of coincident ion.

A doubly skimmed, seeded molecular beam of limonene enantiomer samples (obtained from Sigma Aldrich and used without further purification) was produced after passing Ne gas (0.1 bar backing pressure) through an external stainless steel bubbler maintained at room temperature. The output of a 3 kHz repetition rate laser (Spectra Physics) was frequency doubled in a BBO crystal providing of ~20 μJ, 150 fs pulses at 420 nm, loosely focussed into the molecular beam. Circular polarization was obtained with a λ/4 waveplate and was switched between left- (LCP) and right- (RCP) circular polarization every 500 s. Stokes parameters were determined by polarimetry measurements12: confirming a high degree of circular polarization (|S₃| ≥ 0.975). Measurements on R- and S-enantiomers were accumulated during 49.5 and 45 million laser shots respectively and the average number of electron events per laser shots in both measurements was maintained at 0.085 to minimise false coincidences. For each enantiomer the accumulated counts were reduced to the number released into the
Physical Chemistry Chemical Physics

forward (F) and backward (B) hemispheres, combining the LCP and RCP data in such a way that any residual forward-backward instrumental asymmetry (which is independent of polarization) is cancelled. Then, the PECD asymmetry is conveniently expressed as

\[ G = 4 \left( \frac{F - B}{F + B} \right) \]  

(1)

Fig. 1 shows a ToF mass spectrum which was the same for either polarization and both enantiomers. While the parent ion mass is the dominant species there is a range of smaller daughter ions present. The adiabatic ionization potential of limonene, 8.521 eV, is well established and so ionization requires three 420 nm photons (equivalent energy 8.86 eV). This leaves a maximum excess energy of 0.34 eV available for the photoelectrons. On the other hand, VUV ionization at 9 eV produces negligible fragmentation suggesting that there may be partial uptake of at least a fourth photon by some of the fragmentation channels observed here.

![Mass spectrum of S-limonene seeded in 0.1 bar Ne after ionization by 420 nm 150 fs laser. The parent ion is m/z 136.](image)

Fig. 1

Fig. 2 shows the photoelectron kinetic energy distributions derived from the 3D electron momenta for all detected electrons, and for electrons coincident with selected parent and fragment ion masses. Again these results do not vary with either polarization or enantiomer. These photoelectron spectra are essentially identical to one another, suggesting a common ionization path for both parent and fragment ions, although the fragment ion-tagged spectra do tail slightly more to high energy suggesting that a small subset of the fragmentation may arise from more energetic ionization processes. The range of kinetic energy observed is nevertheless broadly consistent with a net three photon ionization, although the peak in the distribution is significantly below the 0.34 eV expected at the adiabatic ionization limit. Before further assigning the dominant ionization process we consider the assignment of the resonant intermediate state accessed in our experiments.

The UV absorption, and corresponding circular dichroism (CD) of limonene vapour in the range 225 nm — 150 nm was first reported by Brint et al. (see Fig. 3). Subsequently, the absorption spectrum has been re-measured at slightly higher resolution and extended down to ~120 nm. Above 200 nm the absorption spectrum displays a weak pedestal, albeit with a few broad structures. Brint et al assigned the first feature, at 218 nm (5.69 eV), to excitation from the \(2\pi\) HOMO, located at the C=C double bond in the cyclohexene ring. The assignment of the upper level as the \(3\sigma\) Rydberg state was based upon the observed 22915 cm\(^{-1}\) term value of this excitation. A second weak feature at 210 nm (5.90 eV), also clearly visible in the CD spectrum, was assigned to the same electronic transition with one quantum of vibrational excitation, probably in the ring C=C stretching mode. A third feature at 204.9 nm (6.051 eV), this more prominent in the CD spectrum, was tentatively assigned as being the same excitation but having two quanta in this C=C stretching mode.

![Photoelectron kinetic energy distributions of limonene measured at 420 nm for all-, and for mass-tagged-electrons, as indicated.](image)

Fig. 2

On the other hand, making use of the high level EOM-CCSD method and a cc-pVDZ basis with additional molecule-centred diffuse functions, Smialek et al. calculated that excitations to the \(3\sigma\) and higher Rydberg series occur at somewhat higher energies, starting with the \(2\pi\rightarrow3\sigma\) transition at 6 eV. Additionally, they calculate transitions from the second highest \(1\pi\) molecular orbital (located at the isopropenyl double bond) to \(n=3\) Rydberg series starting at 6.39 eV. However, accepting these suggested excitation energies leaves unaddressed a question concerning the identity of the absorptions in the pedestal region below 6 eV. The assignment offered by Brint et al. would suggest that our current choice of 420 nm wavelength is two photon resonant (equivalent energy of 5.90 eV) with the \(2\pi\rightarrow3\sigma\) \((v=1)\) excitation feature seen in both absorption and CD spectra (see Fig 1). The inferred energy of the excited vibrational mode is ~1500 cm\(^{-1}\) (0.186 eV). In the \(2\pi\) \(^1\) cation ground state, the principal vibrational progression observed in both threshold and He I photoelectron spectra has a first spacing of 0.174 eV and the mode has been assigned as the ring C=C stretch. Assuming this is the same mode excited in the Rydberg intermediate and a \(\Delta\nu=0\) propensity for the Rydberg state ionization, the required ionization energy is then that for the \(2\pi\) \(^1\) \((v'=1)\) cation, determined as 8.695 eV from the He I photoelectron spectrum. At the 420 nm three photon energy equivalent of 8.856 eV this then leaves an excess energy of just 0.16 eV. This accords reasonably well with the experimental electron energy distribution (Fig. 2) peaking at ~0.1 eV, from which we deduce a
dominant two photon resonant, three photon (2+1) ionization mechanism producing \( \nu' = 1 \) cation in the current experiment. This argument also tends to support the \( 2\pi \rightarrow 3s(\nu' = 1) \) assignment of the 5.9 eV peak. Further post-ionization photon absorption by the cation states most probably accounts for the extra fragmentation noted.

![Figure 3](image3.png)

**Fig. 3** UV CD\(^a\) and absorption\(^b\)\(^–\)\(^19\) spectra of limonene vapour, arbitrarily scaled to facilitate comparison. CAM-B3LYP/dAug-cc-pVDZ calculated Rydberg excitations for conformers Eq-1 (red), Eq-2 (green) and Eq-3 (cyan) are marked with heights proportional to their oscillator strength. The two photon energy equivalent of the 420 nm fs laser excitation (5.9 eV) is marked, with grey bands indicating the two photon excitation range (derived from the measured laser bandwidth FWHM of 2.55 nm\(^14\)).

To attempt further corroboration of the spectrum assignment we have performed our own TD-DFT calculations using the long-range adjusted CAM-B3LYP and M11 functionals with a double augmented cc-pVDZ basis set at B3LYP/cc-pVDZ optimised geometries, considering the three lowest energy equatorial conformers of limonene, Eq-1, Eq-2, and Eq-3.\(^{20}\) These results and previous EOM-CCSD calculations\(^{19}\) are summarised in Table 1. While there is some spread in the absolute excitation energies calculated, these methods consistently indicate a ~0.4 eV energy gap between the \( 2\pi \rightarrow 3s \) and first \( 2\pi \rightarrow 3p \) excitations and oscillator strengths that are approximately an order of magnitude less for the former transitions.

Guided by these observations we have plotted the CAM-B3LYP transition energies and relative oscillator strengths on Fig. 3 with an empirically chosen -0.1 eV energy offset. Although ignoring e.g. Franck-Condon factors the theory-experimental spectra match with this empirical adjustment is convincing. The calculated \( 2\pi \rightarrow 3s \) excitation is brought into alignment with the 5.7 eV pedestal peak previously so assigned\(^6\) while the steep rise in the VUV absorption spectra, and in particular a weak inflection at 6.12 eV in the higher resolution spectrum,\(^{19}\) coincides with the cluster of \( 2\pi \rightarrow 3p \) and \( 1\pi \rightarrow 3s \) transitions. Similar results are obtained by plotting the EOM-CCSD calculations with an offset of ~0.32 eV. (Systematic studies have found EOM-CCSD can overestimate excitation energies by a few tenths eV, so that this adjustment is not intrinsically surprising.\(^{21}\) Overall, we therefore favour assignment of the transitions in the pedestal region below 6 eV to the \( 2\pi \rightarrow 3s \) electronic excitation, with higher Rydberg excitations falling above this and infer a (2+1) ionization mechanism at 420 nm, producing vibrationally excited cations.

**Figure 4** shows the multiphoton PECD asymmetry obtained for both enantiomers as a function of electron energy. The absolute magnitude is greatest in the vicinity of the peak in the electron energy distribution, and decreases on passing towards faster electrons. The R- and S- enantiomer PECD effectively mirror each other, as would be expected, an observation which also helps establish the molecular origin of the forward-backward asymmetries that are detected. Selecting a photoelectron energy of 0.0 — 0.2 eV that encompasses the photoelectron energy peak region we obtain asymmetry factors of -0.04±0.002 for the R-enantiomer, and +0.046 ± 0.002 for the S-enantiomer, a magnitude about 30-fold greater than the corresponding asymmetry factors previously observed in absorption\(^b\) and ionization yield\(^5\) measurements. There is then a decrease in the asymmetry towards higher kinetic energies which might be expected to correlate with production of vibrational ground state cation, although as noted there is no distinct structure associated with this.

**Figure 4** 420 nm multiphoton PECD asymmetry of limonene enantiomers using all electrons (no mass-tagging). Error bars are derived from Poisson count statistics. Also shown on the same energy scale as a dashed grey line is the normalised photoelectron energy distribution from Fig 2, plotted on the same energy scale (dashed grey line, right hand axis).

**Conclusions**

These preliminary observations of fs laser multiphoton PECD in limonene demonstrate this to be a convenient and, because of the large asymmetry factors, a potentially sensitive approach to enantiomeric identification in conjunction with laser ionization mass spectrometry. They also raise some challenges and opportunities for developing better theoretical insights. First, because of the existence of various conformers of limonene it will be necessary to develop understanding of the plausible conformer populations under experimental conditions and to account for these in computational models, since PECD is known to be exceptionally sensitive to molecular conformation. Secondly, it will be necessary to consider PECD generated not by ionization from ground state neutrals, but from excited Rydberg states, and to account for additional anisotropies introduced in the two photon excitation step. A first extension of successful single photon PECD treatments in this manner, considering the MP-PECD of camphor, provided encouraging results but much remains to be done.\(^{15}\) Thirdly, according to the interpretation offered here this will be the first instance in which PECD is clearly observed from a vibrationally excited state. Recent
evidence suggests that vibronic interactions with odd quanta of vibrational excitation can exert a very dramatic influence on PECD asymmetries\textsuperscript{22, 23} and such possibilities will need to be carefully checked out and validated. Further experiments using different wavelengths and excitation schemes are planned as a contribution towards tackling these challenges and opportunities.
