Aromatic Hydroxylation by an Oxo-bridged Diiron(III) Complex: A Bio-inspired Functional Model of Toluene Monoxygenases

Ambica Kajriwal, a Pinaki Bandyopadhyay a and Achintesh N. Biswas a,b

In biology, aromatic hydroxylation is carried out by a family of heme and nonheme oxygenases, such as cytochrome P450, toluene monoxygenases (TMOs), and methane monoxygenases (MMO). In contrast, a vast majority of synthetic iron based catalysts employed so far in aromatic hydroxylation are monomeric in nature. Herein, we have employed a diferric complex of an aminopyridine ligand, [(bpmen)Fe2O(μ-Ο)(μ-ΟH)](ClO4)2, (2), bpmen = N,N'-dimethyl-N,N'-bis(2-pyridylmethyl)-1,2-diaminoethane) towards aromatic hydroxylation with H2O2 and acetic acid. The diiron(III) complex shows promising reactivity in hydroxylation of benzene and alkylbenzenes with a higher selectivity towards aromatic ring hydroxylation over alkyl chain oxidation. The μ-oxo diiron(III) core has been shown to be regenerated at the end of catalytic turnover. However, mechanistic studies indicate that the diiron(III) complex undergoes dissociation into its monomeric congener and the resulting iron(III) complex mitigates aromatic hydroxylation.

Introduction

Selective hydroxylation of aromatic C-H bonds in a single step is a subject of paramount interest in synthetic chemistry. 1 Till to date, development of effective one step process for the conversion of aromatic compounds into their hydroxy derivatives has remained elusive, primarily due to the oxidant resistant nature of the aromatic compounds. 2 For example, oxidation of benzene to phenol in large scale is achieved by the proton catalyzed cleavage of cumene hydroperoxide, which also yields acetone as a significant by-product. 3 Moreover, this cumene process is energy intensive and produces phenol in only 5% overall yield. Thus, development of single step, selective and co-product free process for aromatic hydroxylation under ambient condition remains a challenging task for the synthetic chemists. 4 However, the ability of several metalloenzymes to catalyze aromatic hydroxylation using dioxygen provides necessary impetus to the chemists to design suitable metal catalysts for activating C(aryl)-H bonds. In nature, aromatic hydroxylation is catalyzed mainly by iron containing monoxygenases and dioxygenases. In particular, the diiron hydroxylases such as methane monoxygenase (sMMO), toluene-4-p monoxygenases (T4MO) exhibit remarkable catalytic reactivity towards aromatic hydroxylation. 5

Model systems have been developed in parallel to contribute the understanding of their mechanisms of action and eventually to mimic their activities. In particular, several iron(II) complexes have emerged as promising catalysts to affect aromatic hydroxylation with activated oxygen surrogate such as hydrogen peroxide. 6-10 Among them, the iron(II) complex [Fe(bpmen)(CH2CN)2](ClO4)2 (1; bpmen = N,N'-dimethyl-N,N'-bis(2-pyridylmethyl)-1,2-diaminoethane, Scheme 1) has emerged as one of the most successful mononuclear iron-based catalyst in promoting aromatic hydroxylation with H2O2 and acetic acid. 7 In this case, the authors identified the formation of an Fe(III)-OOH species, which is proposed to generate a highly active oxoiron species via an acid-assisted O-O cleavage. 7a The inability of independently generated bpmen-Fe III 18O in promoting aromatic hydroxylation led the authors to propose...
a somewhat different mechanistic pathway is operative in this catalyst retains its μ-oxo diiron(III) core during catalytic to that of PDP*, formation of putative oxoiron(V) species in crux of the present investigation is to examine whether the Materials and Instrumentation

1

Thus, the identity of the true oxidant in aromatic hydroxylation by complex \( \text{H}_2\text{O}_2/\text{AcOH} \) system remains speculative till date. Very recently, Talsi and co-workers have provided convincing EPR evidence supporting the formation of a formal oxoiron(V) species from dinuclear iron(III) complexes (bearing aminopyridine ligands TPA* and PDP*, TPA*=tris(3,5-dimethyl-4-methoxy-2-pyridylmethyl)-1,2-diaminoethane) was synthesized following the literature method.\(^{15}\) \(^1\)H NMR (300 MHz, CDCl\(_3\)): \( \delta = 2.27 \) (s, 6H, \(-\text{N}-\text{CH}_3\)), 2.66 (s, 4H, \(-\text{CH}_2-\text{CH}_2-\)), 3.69 (s, 4H, N-\text{CH}_2-Py), 7.1-8.54 (m, 8H, Py ring). The synthesis of the metal complex was carried out according to the published procedure.\(^{16}\) ESIMS: m/z: 392 (100%) [M-2ClO\(_4\)]\(^2+\).

Reaction Conditions for catalytic experiments

A total of 20 µL of a 1.0 M \( \text{H}_2\text{O}_2 \) solution (diluted from a 30% \( \text{H}_2\text{O}_2 \) solution) in \( \text{CH}_3\text{CN} \) was delivered all at once in air to a \( \text{CH}_3\text{CN} \) solution (2.0 mL) containing iron 1 mM catalyst and 300 mM aromatic substrate. The final ratio is catalyst: substrate: oxidant=1:300:10. In various experiments, acetic acid (1 equiv w.r.t. the catalyst) was added to the initial solution prior to the addition of oxidant. The solution was stirred for 15 mins. In all cases, the resulting solutions were treated with acetic anhydride (1.0 mL) together with 1-methylimidazole (0.1 mL) to esterify the diol products. Iodopentafluorobenzene was added as an internal standard. Organic products were extracted with CHCl\(_3\), and the solution was washed with 1M \( \text{H}_2\text{SO}_4 \), sat. NaHCO\(_3\), and \( \text{H}_2\text{O} \). The organic layer was dried with MgSO\(_4\) and the solution was subjected to GC analysis. The products were identified by comparison of their GC retention times with those of authentic compounds. All experiments were run at least in duplicate, the reported data being the average of these reactions.

Kinetic Measurements

Kinetic measurements were performed in the UV-Vis spectrophotometer using 2 as catalyst with 300 mM benzene and hydrogen peroxide (10 mM) at 298 K. The formation of the 650 nm band was monitored with time. The experimental data fitting and calculation of the rate constants were performed by Origin 9.0 software. The activation enthalpy and entropy for hydroxylation of benzene were calculated from Eyring plot.

Results and discussion

Catalytic aromatic hydroxylation by complex 2/\( \text{H}_2\text{O}_2 \)

The diiron(III) complex \([\text{bpmen}]_2\text{Fe}_2\text{O}_2(\mu-\text{O})(\mu-\text{OH})[\text{ClO}_4]_3 \) (2), is stable in air and is known to undergo ring opening in presence of water.\(^{16}\) The reactivity of complex 2 towards oxidation of arenes with mild \( \text{H}_2\text{O}_2 \) at room temperature has been evaluated. In a typical reaction, complex 2 (1.0 mM) is dissolved in anhydrous acetonitrile at 298K, benzene (300 equiv. w.r.t. 2) is added and the reaction is initiated by adding \( \text{H}_2\text{O}_2 \) (10 equiv. w.r.t. 2). After stirring the reaction mixture for
15 min, the products have been acetylated by 1-
methyliimidazole/\textit{Ac}_2\textit{O} (as described elsewhere) before their iden-
tification and quantification by GC. Under this condition, phenol has been obtained in 14.0% yield based on the ini-
tial oxidant concentration along with p-quinone (< 1.0 %) as the minor product. Overall selectivity for phenol production has been estimated to be > 99.0% (Entry 1, Table 1). A slightly higher yield of phenol (20.0%) is obtained when the reaction is carried out in presence of acetic acid (1.0 equiv. w.r.t. 2). As evident from Table 1, the diron complex (2) emerges as a better catalyst compared to its monomeric congener (1) (Entry 7 & 8, Table 1) towards benzene hydroxylation under identical reaction condition.\textsuperscript{7a}

In order to gain further insight into the mechanism, toluene is used as the substrate. Toluene offers both aromatic and aliphatic C-H bonds with different bond strengths (88 kcal/mol for C-H vs. 113.5 kcal/mol for p-H-C\textit{Me}_2\textit{H})(17). Preferential oxidation of aliphatic C-H bond in toluene indicates an initial hydrogen abstraction process, whereas, higher selectivity towards aromatic ring oxidation over aliphatic C-H oxidation suggests the involvement of highly electrophilic oxo-metal transient reacting with the aren\textpi-system.\textsuperscript{18} In the present case, oxidation of toluene afforded the cresols as the main product (10% based on H\textsubscript{2}O\textsubscript{2}) along with 2.1% benzaldehyde (Entry 3, Table 1). This corresponds to 79% selectivity for ring oxidation. Moreover, in presence of acetic acid, 2/H\textsubscript{2}O\textsubscript{2} exhibited a clear preference towards ring hydroxylation over aliphatic hydroxylation (12:1) (Entry 4, Table 1) clearly indicating an electrophilic mechanism, presumably by a putative oxoiron(V) species operative during catalytic turnovers. Oxidation of ethylbenzene by 2/H\textsubscript{2}O\textsubscript{2} system also exhibits similar product profile (Entry 5 & 6, Table 1). 2/H\textsubscript{2}O\textsubscript{2} is found to oxidize ethylbenzene in 11% yield to a mixture of 2-ethylphenol, 4-ethylphenol and 1-phenylethanol. The ratio of products derived from aliphatic chain oxidation and aromatic hydroxylation is found to be ca. 1:2. It is interesting to note that the monomeric iron(II) catalyst 1 with H\textsubscript{2}O\textsubscript{2} was shown to promote preferential hydroxylation of methylene group than ring hydroxylation in ethylbenzene (1-phenylethanol/ethylphenols ~4:1) in absence of acetic acid additive.\textsuperscript{7a} Thus, the results indicate that somewhat different reaction pathways are operative in aromatic hydroxylation by 1/H\textsubscript{2}O\textsubscript{2} and 2/H\textsubscript{2}O\textsubscript{2}.

### Mechanistic aspect of aromatic hydroxylation

So far, only a limited number of nonheme iron-complexes have been reported to mediate aromatic hydroxylation with peroxides. In case of mononuclear iron(II) complexes bearing either N4 or N5 donors, high-valent oxo-iron species has been suggested as the active oxidant.\textsuperscript{6,7} The involvement of ‘putative’ iron(V)-oxo intermediates in arene hydroxylation is proposed independently by Banse et al.\textsuperscript{6} and Akimova et al.\textsuperscript{7} Recently, an Fe\textsuperscript{II} NHC complex is also shown to be effective in hydroxylation of benzene and toluene with hydrogen peroxide as the oxidant.\textsuperscript{9} Based on the observation of inverse KIE and high regio- and chemoselectivity observed, the authors argued in favour of an electrophilic attack by a high-valent Fe=O on the aromatic ring. Moreover, aromatic hydroxylation of the coordinated ligand is also observed in some cases, which emphasize the importance of positioning of the substrate near the oxo-metal transient.\textsuperscript{19} Interestingly, a triplet iron(IV)-oxo species is proposed as the key oxidant in intra-molecular aromatic hydroxylation by experimental and theoretical study. Given the fact that a vast majority of nonheme iron(IV)-oxo complexes exhibit sluggish reactivity,\textsuperscript{20} the results provide significant insight regarding the role of secondary coordination sphere in modulating the reactivity of metal-oxygen intermediates. Therefore, despite some notable

\textsuperscript{8} Reaction condition: 2 (1.0 mM), substrate (300 mM), H\textsubscript{2}O\textsubscript{2} (10 mM) in acetonitrile at 298K, Reaction time 15 min (See experimental section for details). \textsuperscript{9}AcOH (1.0 equiv. w.r.t. 2) was added prior to the addition of H\textsubscript{2}O\textsubscript{2}; \textsuperscript{d}Yields are based on initial oxidant concentration; \textsuperscript{7a} reference 7a.
The rate of formation of the iron(III) phenolate species in acetonitrile at 298K as were plotted against $H_2O_2$ concentration. Inset: Absorbance changes at 650 nm with time after the addition of $H_2O_2$. 

![Image](https://example.com/image1.png)

**Fig. 1** UV-visible changes for the reaction of 2 (1.0 mM), benzene (300 mM) and $H_2O_2$ (10 mM) in acetonitrile at 298K. Blue line represent the initial UV-vis spectrum of the complex 2 and the green line represent the final spectrum of the iron(III)-phenolate species. Inset: Absorbance changes at 650 nm with time after the addition of $H_2O_2$.

The kinetics of benzene hydroxylation were determined by plotting the first-order rate constants measured at different temperatures (298-313K) against $1/T$ (Figure 3); the activation enthalpy and entropy values were estimated to be $\Delta H^\# = 66.6 \text{ KJmol}^{-1}$ and $\Delta S^\# = -79.8 \text{ Jmol}^{-1}K^{-1}$. The high activation enthalpy and large negative activation entropy are consistent with a bimolecular rate-limiting step (Eq. 1).

**Rate = k [H_2O_2]**  

(Eq. 1)

The kinetics of benzene hydroxylation by $2/H_2O_2$ differ significantly from the kinetic results obtained previously using nonheme iron(II) complexes with $H_2O_2$ in aromatic hydroxylation. The intermediacy of a monomeric iron(III)-hydroperoxide species in aromatic hydroxylation by nonheme iron(II) complexes and $H_2O_2$ has previously been observed separately by Akimova et al. and Banse et al. The formation of the phenolate in these systems has been shown to follow a two-exponential process; the first process corresponds to the formation of iron(III)-hydroperoxide species whereas rate-determining formation of a true oxidant is believed to be associated with the second process. In the present investigation, linear dependence of rate on $H_2O_2$ concentration seems to exclude the formation of a mononuclear iron(III)-hydroperoxide species in the rate-determining step. To further confirm this hypothesis, we attempted to detect such species in aromatic hydroxylation by $2/H_2O_2$ by UV-visible spectroscopy and in situ ESI-MS study. However, upon addition of $H_2O_2$ to an acetonitrile solution of 2 did not generate the monomeric the iron(III)-hydroperoxide in the temperature range of 0-25°C as evident from the absence of a characteristic bands in the range of 500-560 nm. Furthermore, no peaks
corresponding to this species is detected during the in situ ESI-MS analysis (Figure S1a, Supporting Information). The results are also consistent with the formation of phenolate-bound iron(III) following a single-exponential process in the present case (Figure 1 & 2). The results encouraged us to investigate the fate of the oxo-bridged diiron(III) core during catalytic aromatic hydroxylation. The electronic spectra obtained after the complete decay of the 650 nm is compared with that of the starting complex (2) in Figure 3. The final spectrum exhibits new bands around 350, 430 and 512 nm. The decay of the absorption band at 512 nm is indicative of the rupture of µ-oxo diiron motif during the reaction. However, the final spectrum is strikingly similar to that of [(bpmen)(H₂O)Fe(µ-O)Fe(OH)(bpmen)]²⁺ previously observed by Poussereau et al. upon addition of water to an acetonitrile solution of complex 2. Thus, it is reasonable to believe that the oxo-bridged diiron(III) (2) first dissociate in solution to form mononuclear species as the regeneration of the Fe(III)-(µ-O)-Fe(III) core after the catalytic turnovers. Interestingly, the final complex (2') has been found to mediate further aromatic hydroxylation when a second batch of benzene (300 mM) and H₂O₂ was added at the end of the reaction. Formation of the 650 nm band is seen (Figure S3, Supporting Information) and the spectroscopic yield of the phenolate bound iron(III) is found to be comparable with that observed during the first addition.

The origin of the reactivity of the oxo-bridged diiron(III) complex (2) towards aromatic hydroxylation remains to be elucidated. However, preliminary studies undertaken in this work have revealed some interesting mechanistic puzzles. Firstly, the final complex obtained after catalytic aromatic hydroxylation by 2/H₂O₂ in acetonitrile has been found to contain (µ-O)diiron(III) structural motif. Secondly, the regenerated complex (2') has been found to mediate hydroxylation of benzene with H₂O₂.

In order to explain the results, we have considered several mechanistic hypotheses which are outlined below (eq. 1-4).

Mechanistic work on the mechanism of toluene-4-monoxygenases have revealed that the diiron(III) resting state of the enzyme is first reduced by 2-electron transfer from an NADH-dependent reductase and the reaction between the resulting diiron(II) species with dioxygen results in the formation of a high-valent diiron(IV) species (Complex ‘Q’) which hydroxylates the aromatic ring of toluene via a rebound mechanism. In recent years, structurally similar high-valent diiron species have been characterized. Que and coworkers identified a diamond core species, FeⅢFeⅣ(µ-O), supported on a tripodal N₄ ligand. The species has been found to yield the valence-localized [OH-FeⅢFeⅣ(µ-O)FeⅣ=O] species. The latter species featuring an S=2 terminal iron(IV)oxo has already been shown to be highly reactive in cleaving C-H bonds. Based on these results, formation of similar high-valent diiron(III) species based on N₄-bpmen ligands can be envisioned. However, in absence of literature precedence of the involvement of similar species in metal complex catalyzed aromatic hydroxylation, rigorous spectroscopic data is needed to substantiate the claim.

The second possibility indicating the involvement of a mononuclear ferric hydroperoxo species as the active oxidant is less likely to be true. A number of nonheme ferric hydroperoxo species have already been generated and characterized. They have been found to be sluggish oxidants and therefore, less like to cleave C(aryl)-H bonds directly. More recently, studies by Banse et al. have shown that the ferric hydroperoxo species undergo homolytic cleavage to generate more reactive iron(IV) oxo transients capable of cleaving C-H bonds. However, in aromatic hydroxylation by 2/H₂O₂, this possibility can be safely excluded on the basis of the lack of reactivity of independently generated [FeⅣ=O]bpmen towards C(aryl)-H bonds.

The fourth scenario considers the heterolytic cleavage of the peroxo linkage in Fe(III)-OOH to generate a ‘putative’ iron(IV) oxo species. Although similar iron(V) oxo species have rarely been detected, theoretical studies have indicated their superior oxidative reactivity in cleaving strong C-H bonds. Moreover, involvement of high-valent oxoiron(V) intermediate has previously been proposed for benzene hydroxylation by monomeric [FeⅣ=O]bpmen)²⁺ (1) and H₂O₂ by Akimova and co-workers. In the present case, arene hydroxylating ability of complex 2 and H₂O₂ can be explained considering spontaneous dissociation of the diiron(III) complex into a monomeric ferric...
considering the dissociation of diiron(III) complex (2) is EPR silent due to the presence of two antiferromagnetically coupled Fe(III) centres. Addition of 10 equiv. of H₂O₂ to an acetonitrile solution of complex 2 (1 mM) at room temperature and freezing the mixture at -78°C, the EPR spectrum (Figure S4, ESI) is found to exhibit a signal at g = 4.23, which can be tentatively assigned to a high-spin mononuclear iron(III) complex. Moreover, the spectrum also indicates the presence of at least two S=1/2 species in the mixture (Figure S4). The resonances at g₁ = 2.15, g₂ = 2.15 and g₃ = 2.08 can be rationalized either by considering the formation of a low-spin ferric hydroperoxo intermediate or a binuclear Fe(III)Fe(III) complex with antiferromagnetically coupled Fe(III) (S = 3/2) and a low-spin Fe(III) (S=1) unit. The second set of signals appears at g₁ = 2.06, g₂ = 2.01 and g₃ = 1.96. Both the S=1/2 signals have been found to decay with time. It is noteworthy that an S=1/2 EPR signal similar to the latter has recently been detected by Talsi et al. in reactions between structurally related oxo-bridged diiron(III) complex and H₂O₂ at low temperature. The EPR spectrum obtained after the addition of excess benzene to 2/H₂O₂ mixture (Figure S4, ESI) exhibit a S=3/2 signal at 4.26, which can be assigned to the phenolate-bound iron(III) complex. A broad S=1/2 signal is also observed in this case. The formation of mononuclear species is also evident from the in situ ESI-MS study. ESIMS spectrum obtained after addition of H₂O₂ to an acetonitrile solution of 2 (1 mM) and excess benzene (Figure S1a & S1b, ESI), exhibits prominent peaks at m/z = 342, 361 and 478. The first two peaks are assignable to [(bpmen)FeO(OOH)(MeCN)]⁺ and [(bpmen)Fe(μ-O)(OH)(OH₂)]⁺. The peak at m/z = 478 corresponds to the phenolate-bound iron(III) species, [(bpmen)Fe(O(Ph)(OH)(MeCN)+H)⁺. Based on these experimental observations, the arené hydroxylation ability of 2/H₂O₂ can be rationalized by considering the dissociation of diiron(III) complex (2) to generate a monomeric high-spin iron(III) species. This step is followed by the formation of a transient ferric hydroperoxo species. Heterolysis of the O-O bond in the ferric hydroperoxo complex is believed to generate a ‘putative’ oxoiron(V) intermediate capable of oxidizing C(aryl)-H bonds.

Conclusions

In conclusion, we report the aromatic hydroxylation of benzene and alkylbenzenes by a nonheme diiron(III) complex [(bpmen)₂Fe₂O(μ-O)(μ-OH)][ClO₄]₂ (2) with H₂O₂ as the oxidant at room temperature. No intermediate mononuclear iron(III)-hydroperoxide is detected during arené hydroxylation. The rate of aromatic hydroxylation has been found to depend on initial concentration of H₂O₂. The results indicate that the reactivity of the diferric complex (2) differs significantly from that of its monomeric congener (1). High selectivity towards aromatic ring oxidation over the alkyl chain oxidation in toluene and ethylbenzene suggest the involvement of electrophilic high-valent oxoiron species as the true oxidant. The μ-oxo diiron(III) core in complex 2 is found to be regenerated after the catalytic turnovers. The diiron(III) complex first dissociates in solution to form a mononuclear iron(III) species, which ultimately generates highly reactive oxoiron(V) intermediate capable of oxidizing aromatic C-H bonds. Although, the aromatic hydroxylation mitigates through monooiron species, regeneration of the μ-oxo diiron(III) core at the end of the catalytic turnover makes the diiron(III) complex (2) a functional mimic of toluene monooxygenases (TMOs). The results reported in this study are believed to stimulate further research aimed at the unambiguous identification of the key high-valent oxoiron transients.
