This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
When the Inhibitor Tells More than the Substrate: the Cyanide-Bound State of a Carbon Monoxide Dehydrogenase

Alexandre Ciaccafava,‡* Daria Tombolelli,‡ Lilith Domnik, Jochen Fesseler, Jae-Hun Jeoung, Holger Dobbe, Maria Andrea Mroginski, Ingo Zebger, Peter Hildebrandt

The Carbon Monoxide Dehydrogenase (CODH) is a key enzyme for reversible CO interconversion. To elucidate structural and mechanistic details of CO binding at the CODH active site (C-cluster), cyanide is frequently used as an iso-electronic substitute and inhibitor. However, previous studies revealed conflicting results on the structure of the cyanide-bound complex and the mechanism of cyanide-inhibition. To address this issue in this work, we have employed IR spectroscopy, crystallography, site directed mutagenesis, and theoretical methods to analyse the cyanide complex of the CODH from Carboxydoterminus hydrogenoformans (CODHIio). IR spectroscopy demonstrates that a single cyanide binds to the Ni ion. Whereas the inhibitor could be partially removed at elevated temperature, irreversible degradation of the C-cluster occurred in presence of excess cyanide on the long-minute time scale, eventually leading to the formation of [Fe(CN)]− and [Ni(CN)]2− complexes. Theoretical calculations based on a new high resolution structure of the cyanide-bound CODHIio indicated that cyanide binding to the Ni ion occurs upon dissociation of the hydroxyl ligand from the Fe2 site of the C-cluster. The hydroxyl group is presumably protonated by Lys563 which, unlike to His93, does not form a hydrogen bond with the cyanide ligand. A stable deprotonated c- amino group of Lys563 in the cyanide complex is consistent with the nearly unchanged C≡N stretching in the Lys563ALA variant of CODHIio. These findings support the view that the proton channel connecting the solution phase with the active site displays a strict directionality, controlled by the oxidation state of the C-cluster.

Introduction

The O2-sensitive [Ni-Fe] Carbon Monoxide Dehydrogenase (CODH) is a homodimeric enzyme responsible for the biological interconversion between CO and CO2 according to the reaction: CO+H2O ⇌ CO2+2H+2e−. CODHs play crucial roles in various metabolic pathways, including the Wood-Ljundahl pathway that allows anaerobic microorganisms, such as acetogenic firmicutes, to oxidise CO using it as source of electrons and various metabolic pathways, including the Wood-Ljundahl pathway that allows anaerobic microorganisms, such as acetogenic firmicutes, to oxidise CO using it as source of electrons.

The CODH hosts a unique [NiFe3S4O3Hx] cluster, called C-cluster, which efficiently catalyses the reversible CO oxidation reaction. Briefly, the C-Cluster resembles a classical cubane shape [4Fe-4S] from which one Fe is pulled out and left to dangle. The dangling Fe, so called Fe1, presumably binds a hydroxyl ligand while the vacant Fe position has been filled by a Ni atom. The C-cluster adopts at least two different oxidation states during catalysis. The Cred2, obtained by a further, two-electron reduction, specifically targets CO2. The midpoint potential of Cred2/Cred1 couple (-530 mV vs SHE) almost matches the midpoint potential of the substrates (ECO/CO2 ≈ -558 mV, pH 7). Moreover, turnover frequencies up to 40000 s⁻¹ and Michaelis constants of ~ 20 µM have been reported for CO oxidation by two CODHs from thermophilic bacteria Ch and whereas the corresponding values for CO2 reduction by the CODH of Rhodospirillum rubrum were found to be ca. 45 s⁻¹ and 200 µM, respectively.

Important information about the catalytic cycle was obtained by X-ray crystallography. Particularly, the recent atomic-resolution structures of CODHIio (dmin ≤ 1.1 Å) provided insight into binding and activation of CO2 (and its inhibitory counterpart NCO). Notably, both CO2 and NCO had undergone a two-electrons reduction step and the respective products were stabilised via π-backbonding. Such a detailed picture is yet not available for CO binding to the C-cluster, although structural analysis pointed to a bent geometry of CO (or formyl) bound to the terminal Ni in the CODH-CO complex.

Inhibition procedures described below are performed under anoxic conditions. Buffers and reagents were anoxically prepared in a glovebox. Sample preparation:

Material and methods

Sample preparation:
Buffers and reagents were anoxically prepared in a glovebox. Inhibitory procedures described below are performed under the same anoxic conditions. In addition to the inherent safety risks while handling cyanide, it is worth noticing that controlling precisely cyanide concentration is not straightforward, especially when using buffer in the physiological relevant range, i.e. pH 7-8, as the pKa value for HCN is 9.21. Therefore, the band position of the C≡N stretching mode ranges from 2080 cm⁻¹ (aqueous CN⁻) to 2093 cm⁻¹ (dissolved HCN), when the pH is decreased below the pKₐ. This is the pH range, where the enzyme exhibits its highest activity. Thus, the absolute concentration effect of CN⁻ has to be estimated with caution. Protein expression and purification were performed as described earlier. Protocol A: 6 μL of CODHICh₄ 400 μM were diluted in 500 μL of buffer A (Tris-HCl 50 mM pH 8, NaCl 100 mM) containing either dithionite (DT) 4 mM or Titanium citrate (Ti(III) citrate) 5 mM and incubated for 45 minutes. Cyanide (1 mM) was added to the sample and allowed to react with CODHICh₄ for 30 minutes under gentle stirring. The CODHICh₄ sample was subsequently washed several times using Microcon® Centrifugal Filters (cut-off 100kDa) with buffer A and reductant in order to remove excess cyanide and finally concentrated to 10 μL prior to injection into the transmission cell. Protocol B: 6 μL of CODHICh₄ 400 μM were added to 6 μL of an inhibition mixture containing cyanide (ranging from 2 to 20 mM) and DT (4 mM) in buffer A. Finally, 10−12 μL of the inhibited CODHICh₄ sample which was prepared according to procedures described above was injected into a gas-tight transmission cell. Protocol C: Crystals of CODHICh₄ were incubated in buffer A’ (25 % PEG3350, 50 mM Tris-HCl pH 8.0 and 5 mM Ti(III) citrate or DT 4 mM). Crystals were then transferred into a buffer B solution containing (25 % PEG3350, 50 mM Tris-HCl pH 8.0, 7 mM DTT), and 0.5 mM of oxidised methylviologen (MV⁺) as electron acceptor for reoxidation. After no further reduction of MV⁺ to the blue colored reduced methylviologen (MV⁻) was detectable, the crystals were incubated in buffer B solution containing 7 mM DTT for 2 hours. Finally, crystals were transferred into a buffer B solution containing 5 mM KCN and loaded into the transmission cell.

Enzymatic assays:
Inhibited aliquots of CODHICh₄ were reactivated under CO atmosphere at 70°C for 30 min. Then the CO oxidation activity was assayed as described before.

Fourier Transform Infrared Spectroscopy:
FTIR spectra were recorded on a Bruker Tensor 27 spectrometer equipped with a liquid nitrogen-cooled MCT detector applying a spectral resolution of 2 cm⁻¹. The sample compartment was purged with dried air, and the sample was held in a temperature-controlled (10 °C) gas-tight IR-cell for liquid samples (volume ~10 µL, path length = 50 µm) with CaF₂ windows. Spectra were base-line corrected by using the OPUS software from Bruker.

Crystallization and manipulation of crystals: CODHII₃ crystals and the −320 mV state were produced as described earlier. Crystals in the −320 mV state were incubated with 70 mM KCN for 30 min. CN⁻-soaked crystals were shock-frozen in liquid nitrogen, generating the −320 mV state. The first one, with pdb: 5FLE, represents the starting from two crystal structures of the CODHII₃-CN⁻ state, with 15 % (v/v) 2R, 3R-butanediol (Sigma) serving as cryoprotectant.

Data collection, structure solution and refinement: Diffraction data were collected at 100 K at a wavelength of 0.9184 Å at BESSY II (Berlin, Germany). The synchrotron data set was integrated and scaled using XDSSAP. Data statistics are reported in Table S1 (see supporting information). Initial rigid body refinement was used to solve phasing, followed by a simulated annealing refinement to minimise model bias using PHENIX. Models were built and refined with COOT. Positional and temperature factor refinements were carried out using Refmac5. New parameters for the C-cluster were generated by iterative cycles of refinement using Refmac5. Individual occupancies of atoms from the C-cluster were adjusted until comparable B factors of atoms were obtained. In the final refinement cycles the B factors were refined anisotropically and alternative conformations of several side chains and Fe₃ were included. The final refinement statistics are shown in Table S1 of ESI. The atomic coordinates have been deposited in the Protein Data Bank, www.pdb.org (PDB ID: 5FLE).

Theoretical methods: The eight structural models listed in Table 2, were built starting from two crystal structures of the CODHII₃ in the −320mV state. The first one, with pdb: 5FLE, represents the CN⁻ bound state refined in this work, while the second structure is inhibitor free (pdb: 3B53). In the latter one, a starting geometry for the CN⁻ bound state was generated by attaching a CN⁻ ligand to the Ni atom. The protein was solvated in an explicit TIP3P water box of dimension 130 x 130 x 130 Å³. Hydrogens were inserted and protonable side chains were set to their standard states at pH 7. Protonation states of some specific residues, e.g. those in the vicinity of the C-cluster or involved in suggested proton transfer pathways, required special attention based on chemical sense and visual inspection. Although the His93 was doubly protonated on Nδ and on Ne, further investigation was required to test different protonation states of this residue together with Lys563, since they are interacting via hydrogen bonds with the non-proteic ligands at the active site. First, 20000 steps of energy minimization were performed using NAMD with the CHARMM22 force field. Hydrogen positions and orientation of water molecules were optimised. Heavy atoms were kept fixed to their initial positions, in order to obtain a good starting point for the subsequent geometry optimization and, at the same time, to remain as close as possible to the crystal structure conformation. Due to the lack of specific force field parameters, the five metal clusters (three standard [4Fe–4S] and two [NiFe₂S₄–Fe]) were initially kept fixed during the energy minimization steps. Charges for the metal clusters were computed with DFT methods while Van der Waals parameters were taken from values reported for similar systems in the literature. The structure resulting from the last minimization step was then refined through hybrid QM/MM calculations, performed within the ChemShell environment. The program interfaces to a variety of QM and MM codes. In our work, Turbomole was chosen as the quantum chemical program while the MM uses DL_POLY with CHARMM22 force field. The system was divided in three layers, each of which treated at a different level of theory and accuracy. The QM part consists of (1) the [NiFe₂S₄] C-cluster and the iron Fe₃; (2) Cys295, Cys333, Cys446, Cys476 and Cys526, which coordinate the Fe atoms of the cluster; (3) His261, which is interacting with Fe₂; (4) all the other non-proteic ligands that includes cyanide on Ni in different positions and hydroxyl on Fe₁ in some of the models; (5) His93, Lys563 interacting directly with the non-proteic ligands, Gln332 interacting via hydrogen bond with Lys563 and Ile567 whose role is important regarding the steric hindrance exerted on the cyanide ligand. DFT was employed in the optimization of the QM part, applying the pure density functional BP86 combined with the resolution-of-the-identity ('RI') technique. The def2-TZVP basis set was used for metals (Ni and Fe), while the 6-31G* basis set was employed for all other atoms of the QM part. This combination of a high quality basis set and BP86 functional is able to give both accurate molecular structures and harmonic vibrational frequencies, due to an error compensation that allows direct comparison of calculated harmonic frequencies with experimental ones. The second layer was made up of protein residues and water molecules included in a sphere of 15 Å around the Ni atom of the C-cluster in monomer A. All the atoms in this section were treated in an explicit manner at the MM level and allowed to move during the optimization cycles. For this purpose the HDLC optimiser was employed. The third layer includes the remaining atoms not included in the previous two. This layer was held fixed during the QM/MM geometry optimization. Covalent bonds at the QM/MM border were cut and saturated by hydrogen link atoms. The coupling between QM and MM was computed using electrostatic embedding with a charge-shift scheme. Once optimised, the structures were analysed and compared with the crystal structure. The latter was based on some fundamental geometrical parameters like bond lengths and bond angles. In addition, a tilt angle was defined as the angle between a unit vector with origin in the center of the plane formed by Ni-S-Fe₃-S and a unit vector directed along the Ni-CN bond axis.
Finally the vibrational frequencies of the quantum mechanical part in the optimised conformation were computed in presence of the point charges of the surrounding atoms of the second and third layers. For this purpose the Gaussian09 program was used with the same DFT functional and basis set employed during the optimization.

Results

IR spectroscopic identification of the CN$^{-}$ inhibited state:

After exposure of CODHII$_{Ch}$ to CN$^{-}$ according to protocol A (see materials and methods), a sharp band immediately appears in the C=N stretching region at 2110 cm$^{-1}$ (Fig.2A). The frequency upshift with respect to the free CN$^{-}$ anion (2080 cm$^{-1}$) is expected since Ni is a weak π-donor metal$^{29}$. Band position and intensity are stable for hours. The frequency at 2110 cm$^{-1}$ is significantly higher than for cyanide bound Fe$^{2+}$ heme proteins such as Horseradish peroxidase, microperoxidase and myoglobin (between 2029 cm$^{-1}$ and 2057 cm$^{-1}$), illustrating the rule of electronegativity (Ni>F e)$^{30,31}$. The origin of the band was further proven with labelled $^{13}$CN$^{-}$ (2065 cm$^{-1}$), revealing the expected isotopic shift of 45 cm$^{-1}$ (Fig.2C).

Next, we studied the CODHII$_{Ch}$-CN complex in the crystalline state which was prepared following the same protocol as used for crystallographic analysis. Several of these crystals were loaded into an IR transmission cell (Fig.2B and D). The IR spectra obtained in this way revealed a band at 2110 cm$^{-1}$ that shifts down by 45 cm$^{-1}$ to 2065 cm$^{-1}$ when crystals were incubated with $^{13}$CN$^{-}$. Thus, the frequency (and isotopic shift) of the Ni-bound cyanide of the crystalline complex is the same as for the sample in solution.

Reversibility of CN$^{-}$ binding:

In order to prove the reversibility of the inhibition process$^{32}$, we prepared a batch of inhibited CODHII$_{Ch}$ that we used in parallel for enzymatic activity assay and IR spectroscopy. A classical enzymatic assay for CO oxidation by CODHII$_{Ch}$ based on reduction of methyliologen was performed to evaluate the initial enzymatic activity (see materials and methods). Subsequently, the enzyme was inhibited following protocol A, and afterwards a new enzymatic assay for CO oxidation was performed. The inhibited protein exhibited not more than 5% of the initial CO oxidation activity (Fig.3). In parallel the corresponding enzyme was also loaded into a transmission cell for IR measurement and revealed the characteristic C=N stretching band at 2110 cm$^{-1}$ (Fig.3 inset). Finally, the enzyme was reactivated at 70°C under CO atmosphere for 30 minutes and tested for CO oxidation afterwards. More than 60% of CO oxidation was recovered thereby proving a high reversibility of the CN$^{-}$ binding (Fig.3).

These results are, however, not in agreement with previous IR data published for CN$^{-}$ inhibition of CODHII$_{Ch}$.$^{12-13}$ These authors observed a band at 2037 cm$^{-1}$ (1995 cm$^{-1}$ with $^{13}$CN$^{-}$) and a second absorption appearing only at higher CN$^{-}$ concentration at 2079 cm$^{-1}$ (2037 cm$^{-1}$ with $^{13}$CN$^{-}$). However, the preparation protocol employed in that work did not include the removal of excess cyanide. In fact, when we repeated the experiments upon omitting the final buffer exchange step (protocol B, see materials and methods) we observed several bands at 2124 cm$^{-1}$, 2093 cm$^{-1}$ and 2037 cm$^{-1}$ shifting to 2078 cm$^{-1}$, 2061 cm$^{-1}$ and 1995 cm$^{-1}$ upon exposure to $^{13}$CN$^{-}$, respectively (Fig.4A and B).

While the assignment of the band at 2093 cm$^{-1}$ and its isotopically 32 cm$^{-1}$ shifted counterpart at 2061 cm$^{-1}$ to HCN and $^{13}$CN is straightforward$^{39}$, the origin of the two other bands is less obvious. Since only one binding site for CN$^{-}$ is available in CODHII$_{Ch}$ structure$^{8}$, the presence of two extra bands is surprising. Moreover, these two features appear with a very slow rising time (≥ 5 hours) (Fig.5). In contrast, formation kinetics of the cofactor-cyanide adduct according to protocol A (removal of excess cyanide) and reflected by the 2110 cm$^{-1}$ band is not resolved on the time scale of these
experiments and, hence, must occur on the minute time scale or faster (< 30 min), (Fig. 5).

**CN⁻-induced degradation of the C-cluster:**

Even though CN⁻ has been described as a slow reversible inhibitor, CODHIIₜₙ is fully inhibited in less than one minute at 70°C with 1 mM KCN under turnover conditions and in less than 80 min at 23°C with 0.1 mM KCN under non-turnover conditions as described in a previous study. Furthermore, CN⁻ is known to have a high affinity towards metal ions including Fe and Ni which are the main components of the C-cluster, therefore, we suspected that prolonged exposure of CODHIIₜₙ to CN⁻ might lead to the formation of various cyano-metallic complexes. Therefore, we performed control experiments in order to verify the possible CN⁻ induced degradation of the metal clusters due to prolonged exposure of CODHIIₜₙ to CN⁻.

The corresponding IR spectra were measured under the same experimental conditions as used for CODHIIₜₙ inhibition studies (Fig.6). Thus, nickel chloride (NiCl₂) has been incubated with CN⁻, resulting in the appearance of an absorption band at 2124 cm⁻¹ (2078 cm⁻¹ for ¹⁵CN⁻) (Fig.6B red line), which can be assigned to [Ni(CN)₄]²⁻ complex. In addition, the corresponding cyano complex of iron,[Fe(CN)₄]²⁻, exhibits an absorption band at 2037 cm⁻¹ (1995 cm⁻¹ for ¹³CN⁻) (Fig.6B blue line).

Accordingly, the control experiments allowed an assignment of the three bands observed for CODHIIₜₙ inhibition according to the alternative protocol B. Two of these bands, i.e. at 2080 cm⁻¹ (2036 cm⁻¹ for ¹³CN⁻) and 2037 cm⁻¹ (1995 cm⁻¹ for ¹³CN⁻) at pH8, are readily attributed to aqueous CN⁻ and [Fe(CN)₄]²⁻, respectively. The frequencies agree very well with those reported by Qiu et al. for CODH, although the assignment suggested by these authors can be ruled out. The third band at 2124 cm⁻¹ (2078 cm⁻¹ for ¹³CN⁻) was not reported by these authors although a weak band at ca. 2078 cm⁻¹ can be identified in the published spectrum of the CODH₂⁻¹⁻CN⁻ adduct in the corresponding figure. This band at 2124 cm⁻¹ band is now assigned to the C=N stretching of [Ni(CN)₄]²⁻ (Table 1).

**Parameters controlling the C≡N stretching mode:**

It was suggested previously that, depending on the concentration, cyanide may bind in different modes to the C-cluster. IR experiments were, therefore, carried out using different CN⁻/CODHIIₜₙ molar ratios from large excess (1000/1) to substoichiometric (1/2) amounts. These experiments did not reveal any additional band nor any frequency shifts of the only observed band at 2110 cm⁻¹ (data not shown). Furthermore, another, alternative binding mode was proposed to involve a hydroxyl ligand on the dangling Fe¹⁻⁻, which should be sensitive to the local proton concentration. Thus, cyanide inhibition was studied as a function of the pH.
Table 1: C≡N stretching frequencies observed experimentally for CODHII-CN adducts according to protocol A and B. Control experiments and published data are also reported.

Data taken from literature are written in italic.

Whereas the C≡N frequency at 2110 cm⁻¹ remained unaffected in the pH range from 6 to 10, the related band intensities displayed a bell-like shape with a maximum at pH 8 (Fig. 7). Again, these findings argue against any pH-dependent changes of ligand binding at the C-cluster. Instead, the intensity changes most likely reflect pH-dependent alterations of the active site accessibility for CN⁻.

There are also no qualitative changes of cyanide binding depending on the temperature.

![Fig. 7: Intensity of the C≡N stretching mode at 2110 cm⁻¹ of the CODHII₈₉-CN adduct plotted as a function of the pH. Intensities were normalised with respect to the intensity of the corresponding amide II band.](image)

The C≡N stretching frequency and the band intensity decrease only slightly (by 2.0 cm⁻¹ and ~30%, respectively) upon raising the temperature from 10°C to 60°C (Fig. 8). Conversely, in the frozen state (100 K) the frequency is increased by only 5 cm⁻¹. These spectral variations can be rationalised in terms of subtle conformational changes of the protein in the vicinity of the C-cluster. Consistent with this explanation is the observation that the temperature-dependent changes are fully reversible, underpinning the remarkable stability of the CODHII₈₉-CN adduct.

![Fig. 8: (A) Frequency and (B) intensity changes of the C≡N mode of the CODHII₈₉-CN adduct as a function of the temperature. The arrow tip points to the direction of the temperature steps.](image)

Environmental effects on the C≡N stretching mode:

According to X-ray data, Ni-bound cyanide is in close vicinity to His93 and Lys563 which may interact with the cyanide-bound metal center. We therefore extended the studies to the CODHII₈₉ variant with alanine substitution at the corresponding position. Addition of cyanide to the Lys563A variant displayed a wild-type like IR spectrum since the ν(C≡N) undergoes a downshift from 2110 to 2102 cm⁻¹.

Crystal structures of CN⁻-inhibited CODHII₈₉:
We have determined a new crystal structure of CN\textsuperscript{-} bound CODH\textsubscript{10} (pdb SFLE) at a resolution of 1.23 Å. As expected, the 2009 structure (pdb:3I39, dmin= 1.35 Å) and the new CODH\textsubscript{10} -CN structure are nearly identical with a rmsd for core Ca atoms of 0.14 Å. The main difference between the two structures is the degree of multiple conformations. While the 2009 structure revealed dual conformations for residues starting from the Fe\textsubscript{2} coordinating His-261 down to residue 266 as well as residues in their vicinity, the electron density of these parts agree now with only a single conformation, indicating a more homogenously CN\textsuperscript{-} bound state\textsuperscript{6}.

**QM/MM calculations:**

Two different experimentally determined structures served as starting points for the QM/MM calculations. First, we used the crystal structure of the CODH\textsubscript{10} -CN inhibited state determined in this work (pdb: SFLE). Geometry optimization did not affect the main structural parameters of the C-Cluster and residues surrounding the CN\textsuperscript{-} ligand except for Ni(C(N) bond length, which was predicted to be shorter by 0.11 Å compared to the experimental value (Table 2). A comparably short Ni-C bond length was also reported in a previous QM/MM study by Amara et al.\textsuperscript{11} and recently observed in CO\textsubscript{2} and NCO bound structures\textsuperscript{6}. Also in the previous CODH\textsubscript{10} -CN structure, solved at lower resolution (1.35 Å), a shorter bond length was determined\textsuperscript{6}, in line with the results of an earlier EXAFS study\textsuperscript{32}. In agreement with the experimental structure, the calculations predict the Ni atom in a square planar geometry with a tilt angle of 6.40° of the CN\textsuperscript{-} ligand (See material and methods, section QM/MM for tilt angle definition). In this configuration, the CN\textsuperscript{-} ligand is in hydrogen bonding distance to the side chains of His93 (2.72 Å) and Lys563 (2.98 Å).

Second, calculations were carried out starting with the CODH\textsubscript{10} structure of the -320 mV reduced state (pdb:3B53) to which we added a CN\textsuperscript{-} ligand in silico (CODH\textsubscript{10} -C\textsubscript{red1}-CN). Prior to optimization, we have removed the water molecule in the vicinity of the CN\textsuperscript{-} binding site to keep in line with the experimental structure of CODH\textsubscript{10} -CN. Between both optimised structures a very good agreement was obtained with respect to the geometries of the C-cluster and CN\textsuperscript{-} environment (Table 2). Also for the optimised CODH\textsubscript{10} -C\textsubscript{red1}-CN structure a small tilt angle (3.03 Å) for the CN\textsuperscript{-} ligand and similar distances to His93 (2.74 Å) and Lys563 (2.88 Å) were obtained.

The C=N stretching frequencies were calculated to be 2074 cm\textsuperscript{-1} and 2058 cm\textsuperscript{-1} for CODH\textsubscript{10} -CN and CODH\textsubscript{10} -C\textsubscript{red1}-CN, respectively. They are both significantly lower than the experimental value of 2110 cm\textsuperscript{-1}.

As postulated previously\textsuperscript{7,36}, CN\textsuperscript{-} may initially bind to complete a distorted tetrahedral coordination geometry at the Ni. Thus, an alternative geometry optimization was started by setting the initial tilt angle to 60.71°. In fact, the subsequent energy minimization afforded different minima for both CODH\textsubscript{10} -CN (CODH\textsubscript{10} -CN/tilt) and CODH\textsubscript{10} -C\textsubscript{red1}-CN (CODH\textsubscript{10} -C\textsubscript{red1}-CN/tilt) with somewhat higher tilt angles of ~18°. In these configurations, the nitrogen-to-nitrogen distance of the CN\textsuperscript{-} ligand to Lys563 is significantly increased to 3.8 – 3.9 Å, whereas that to His93 is nearly unchanged. The corresponding calculated stretching frequencies are now much closer to the experimental value (Table 2).

The two optimised active site structures with the more tilted CN\textsuperscript{-} geometries exhibited an open space, which allowed binding of an OH\textsuperscript{-} to Fe\textsubscript{2}. To assess the influence of such a...
ligand on the C–N stretching frequency and to get an equivalent structure of the CN$^-$ inhibited state observed in CODH$_{Mo}$ (pdb: 3I04$^*$), an OH$^-$ ligand was introduced. In these structures (CODHII$_{Ch}$-CN/tilt/OH$^-$; CODHII$_{Ch}$-K563A/CN/tilt/OH$^-$), geometry optimizations caused the tilt angle to increase from ~18° to ~35° because of increased steric interactions, consistent with the experimentally determined tilt angle in CODH$_{Mo}$ (~30°). In addition to the hydrogen bond formed with the Ne of His93, the hydroxyl ligand also provides an extra hydrogen bond to the CN$^-$ molecule thereby contributing to a significant decrease of the stretching frequency down to 2054 cm$^{-1}$ (Table 2).

Whereas in all geometries, His93 remains in H-bond distance, the tilt angle geometry seems to depend on the interactions of the CN$^-$ ligand with Lys593. To assess the role of Lys593, we have generated the CODHII$_{Ch}$-CN/KS63A structure in silico, starting from that of the wild-type protein complex (pdb: 5FLE). Optimization leads to a tilt angle of ca. 24° and the resultant calculated C=N stretching frequency (2112 cm$^{-1}$) agrees well with the experimental frequency of 2102 cm$^{-1}$ (Table 2).

Additional information about the potential interactions of Lys593 with the cyanide ligand was provided by the optimised CODHII$_{Ch}$-CN (wild-type) structure including a deprotonated Lys593 side chain. Also in this case, calculated (2109 cm$^{-1}$) and experimental (2110 cm$^{-1}$) C=N stretching frequencies nearly coincide (Table 2).

**Discussion**

Cyanide-inhibition of Ni-dependent CODHs has been investigated for many years using a variety of experimental approaches. The analysis of the CODH-CN complex is thought to contribute to a better understanding of the catalytic mechanism but, the previous studies did not yet provide a consistent view about the structure of the cyanide-bound active site and its degradation pathway.

**The cyanide binding site:**

Early IR spectroscopic studies revealed two different C–N stretching modes that, due to their dependence on the cyanide concentration, were interpreted in terms of different modes of cyanide binding. Although the previously proposed bridging position between Fe$_3$ and Ni has been meanwhile discarded, the view of two different binding geometries was re-animated on the background of slightly different active geometries derived from X-ray crystallography$^{7,8}$. In an attempt to reconcile crystallographic$^{7,8}$ and spectroscopic data (ENDOR, Mössbauer)$^{18-39}$, a two-step inhibition mechanism was proposed$^{36}$. In the first step, CN$^-$ was suggested to bind reversibly to Ni in a distorted tetrahedral geometry of the coordinated Ni ion as suggested by the crystal structure of CODH$_{Mo}$. This step may be similar to CO binding whereas in the second step, the release of a OH$^-$ ligand of Fe$_3$, previously suggested to bind to C$_{red1}$$^{38}$, is followed by a slow reorganization of the cofactor that allows CN$^-$ to bind more tightly to the C-cluster. This is thought to be reflected by the square planar coordination geometry of Ni observed in CODHII$_{Ch}$. The different CN$^-$ concentrations used for inhibition of both the CODHII$_{Ch}$ and CODH$_{Mo}$ crystals in soaking solutions were suggested to be the origin of these two binding modes.

In the present work, we have now shown that the previously reported frequencies of 2037 and 2079 cm$^{-1}$ do not refer to the cyanide bound to the cofactor but originate from free CN$^-$ (2080 cm$^{-1}$) and the degradation product Fe(CN)$_4^{2-}$ (2037 cm$^{-1}$). Instead, the intact cofactor-CN adduct gives rise to a band at 2110 cm$^{-1}$. This band is observed at the same position for the enzyme in solution and in the crystalline state. Accordingly, the IR spectroscopic data should originate from the same state to which the crystallographic model refers to and which served as the starting point for the theoretical approaches. Specifically, QM/MM calculations indicate that the cofactor-CN adduct is characterised by the lack of an OH$^-$ ligand at the Fe$_3$ as the hydrogen bonding interactions would cause a substantial downshift of this mode by ca. 50 cm$^{-1}$ compared to the experimental value (2110 cm$^{-1}$). A band at such a low frequency that could be ascribed to a Fe$_3$(OH$^-$)Ni(CN$^-$) adduct is not observed at any experimental condition employed in this work. This negative result does not per se rule out the existence of such an intermediate state. However, if it exists, it is not accumulated even at sub-stoichiometric CODHII$_{Ch}$/CN$^-$ ratios and must, instead, decay quite rapidly on the sub-minute time scale to the stable Fe$_3$Ni(CN$^-$) adduct.

**Mechanism of the cyanide inhibition and degradation of the C-cluster:**

Once the CODHII$_{Ch}$-CN complex was formed according to protocol A, i.e. after removal of excess cyanide, it remained stable for hours at 10°C but the cyanide ligand can be removed at elevated temperature in the presence of CO, accompanied with a recovery of the enzymatic activity. Conversely, a large excess of cyanide accelerates the degradation of the cofactor that is observed on the time scale of hours and eventually leads to the formation of the stable [Fe(CN)$_4^{2-}$] and [Ni(CN)$_4^{2-}$] complexes. These findings point to a two-step inhibition mechanism. First, cyanide rapidly binds to the Ni ion and induces the release of the OH$^-$ ligand from Fe$_3$. This process can be reversed at high temperature in the presence of CO. In the second step, an additional cyanide binds to Fe$_3$, albeit with a much slower rate, such that this step and thus the irreversible degradation can be efficiently blocked upon removal of excess cyanide after CN$^-$ binding to Ni (protocol A). Since the IR spectra provide no indication for a C-cluster coordinated by two cyanides, CN$^-$ binding to Fe$_3$ appears to be followed by the rapid decomposition of the cofactor into the [Fe(CN)$_4^{2-}$] and [Ni(CN)$_4^{2-}$] complexes.

**Structure of the CN$^-$cofactor adduct:**

As already shown in previous studies on hydrogenases, the stretching frequency of the metal-bound cyanide ligand depends sensitively on the geometry of the cofactor, its
Accordingly, the oxidation state of the C-cluster controls the binding pocket, including hydrogen bonding interactions and electronic configuration, as well as on the electrostatics in the optimised structures, the N-H atom of His93 remains at a distance of 2.7 Å which, together with the nearly linear (Ni)CN-H-N(His93) geometry, points to strong hydrogen bonding interactions. Conversely, the comparison of calculated and experimental C=N stretching frequencies indicates that the interactions between the cyanide ligand and Lys563 must be weak, corresponding to a relatively large nitrogen-nitrogen distance (4 Å). Such weak interactions point to a deprotonated side chain of Lys563. The potential proton acceptor is readily identified as the hydroxyl ligand of Fe, which is released upon cyanide binding to the Ni. Furthermore, the time-independent frequency and intensity of the C=N stretching indicates that Lys563 remains deprotonated over the time scale of hours, implying that the active site of the cyanide-bound red1 state is not accessible for protons from the solution side via the proton channel identified in CODH₂⁻.  

It might be that structural changes along the proton channel in the cyanide-bound complex may impair reprotonation of Lys563. However, the present structure of the cyanide-complex does not permit an unambiguous conclusion (vide infra). As an alternative interpretation, one may invoke a redox-state dependent proton transfer. This view is consistent with the high turnover number for CO oxidation at the red1 state which requires a rapid and unidirectional proton translocation from the C-cluster to the solution. The reverse proton translocation occurs during enzymatic CO₂ reduction which, in turn, is based on the red1 state. Accordingly, the oxidation state of the C-cluster controls the directionality of the proton transfer such that reprotonation of Lys563 is inhibited in the cyanide complex of red2. 

A deprotonated Lys563, however, is not consistent with the present high-resolution structure of the CODHII-CN complex which displays a distance of only 3 Å, concomitant to a smaller tilt angle, and thus points to appreciable Lys563-cyanide interactions. Whereas X-ray crystallography reflects the protein including a protonated side chain, the IR spectra that are identical in the crystalline state at low temperature and in solution at ambient temperature indicate a deprotonated Lys563 residue. To reconcile these findings, we suggest that, during accumulation of the diffraction data, radiation damage at the C-cluster may cause generation of a hydroxyl radical from a water molecule in the vicinity of Lys563, which is associated with a distinctly lower pKₐ of ca. 11.41 As a consequence, protonation of the Lys side chain could occur.

Conclusions

In the present study we have unambiguously identified the C=N stretching mode of the cyanide bound complex of CODHII, confirming that a single cyanide is bound to the Ni ion. Additional IR bands observed in previous investigations could be attributed to free cyanide or to degradation productions of the C-cluster. This complete cyanide-induced degradation of the Fe-Ni center only occurs in the presence of excess cyanide. In the absence of excess cyanide, the CODHII-CN complex is stable for hours at ambient temperature and enzymatic activity towards CO oxidation can even be recovered at elevated temperature. On the basis of QM/MM calculations the CODHII-CN complex, cyanide binding to the Ni occurs upon release of the hydroxyl ligand from the Fe. The hydroxyl ligand captures a proton from the side chain of Lys563. On the other hand, the present crystallographic data point to a protonated Lys563, which is not compatible with the IR spectroscopic data obtained from CODHII-CN crystals. This discrepancy is suggested to be due to reprotonation of Lys563 via a water radical, generated in situ upon X-ray irradiation. The IR spectroscopic data, however, indicate that in the cyanide complex Lys563 remains deprotonated for hours. This finding prompted us to suggest a redox-state dependent directionality of proton translocation through the proton channel connecting the solution phase with the active site. This interpretation is consistent with the enzymatic processes that require proton release from and proton uptake by the active site in the red1 state (CO oxidation) and red2 state (CO₂ reduction), respectively.

The present results and the proposed interpretations demand for further experimental and theoretical investigations of the proton translocation mechanisms and the protonation pattern of the different active site states during the enzymatic reaction sequences.
