This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Efficient photoluminescent thin films consisting of anchored hybrid perovskite nanoparticles

Laura Martínez-Sarti, Teck Ming Koh, Maria-Grazia La-Placa, Pablo P. Boix, Michele Sessolo, Subodh G. Mhaisalkar and Henk J. Bolink

Methylammonium lead bromide nanoparticles are synthesized with a new ligand (11-aminoundecanoic acid hydrobromide) by a non-template method. Upon dispersion in toluene they show a remarkable photoluminescence quantum yield of 80%. In addition, the bifunctional ligand allows to anchor the nanoparticles on a variety of conducting and semiconducting surfaces, showing bright photoluminescence films with a quantum yield exceeding 50%. This opens a path for the simple and inexpensive preparation of multilayer light-emitting devices.

Recently, organic inorganic (hybrid) lead halide perovskites have been widely studied for photovoltaic applications, where power conversion efficiencies exceeding 22.1% have been demonstrated. Beyond solar cells, these materials are interesting candidates for low-threshold lasers and light-emitting diodes (LEDs). Their application in LEDs requires a precise control over their morphology, since this determines their optical and electronic properties. In particular, materials with high photoluminescent quantum yield (PLQY) are desirable for the preparation of efficient LEDs. One of the most suitable strategies for controlling the morphology and enhancing the photoluminescence of perovskites is the preparation of nanostructured materials. In nanostructured perovskites, the spatial confinement of the charge carriers, together with a passivation of the surface states result in a substantial increase of the luminescence yield when compared to bulk perovskites. The recent breakthroughs in the PLQY of narrow-band emitting perovskite nanoparticle (NPs) (full width at half-maximum, FWHM ~ 20 nm) make these materials promising candidates for light-emitting applications. Perovskite NPs can be prepared by a direct, non-template method that makes use of organic ligands to disperse the material in the form of colloidal NPs. These organic capping ligands are usually medium or long chain alkyl ammonium halides that limit the growth of the material in the three dimensions. Schmidt et al. reported, for the first time, the synthesis of 6-nm sized methylammonium lead bromide (MAPbBr₃) colloidal perovskite NPs using octadecylammonium as the capping ligand. Thin films obtained by spin-coating the NPs dispersion showed intense photoluminescence (PL) with an associated quantum yield of about 20%. Through a modified synthetic conditions, the same group later showed that surface states could be further passivated by insertion of a complementary weak Lewis base, and PLQYs up to 82% in solution were obtained. Recently, color tunable mixed halide perovskite NPs with PLQY in solution up to 93% have been demonstrated. Interestingly, the NPs size was found to be strongly dependent on the synthesis temperature, giving an additional degree of freedom in the material design while, at the same time, underlining the difficulties in achieving reproducible preparation of monodisperse hybrid perovskite NPs. The elimination of polar solvents such as dimethylformamide (DMF) during synthesis has been shown to substantially improve the nucleation and growth of MAPbBr₃ NPs. In general, however, the PLQY drops substantially when the nanoparticles are processed into thin films, due to unavoidable aggregation of the material. In spite of such reduction of the PLQY, these films have been recently used to prepare LEDs. Encouraging brightness and external quantum efficiencies have been shown, further demonstrating the potential of this type of material in lighting and display applications.

In this work, we describe the preparation of highly photoluminescent MAPbBr₃ NPs thin-films, through a temperature-independent synthesis which make use of a bifunctional ligand (11-aminoundecanoic acid hydrobromide, BrNH₃-C₁₀H₂₀-COOH). This molecule efficiently coordinates the NPs and, at the same time, allows to selectively anchor them onto various electroactive surfaces. This approach was then used to construct multi-layer green emitting LEDs.

The 11-aminoundecanoic acid was converted into its ammonium bromide salt (Br NH$_3^+$-C$_{10}$-COOH) to enhance its solubility in DMF. The NPs were obtained taking advantage of the interplay between a polar solvent (DMF, able to solubilize the perovskite precursors) and a non-polar one (toluene), as described in previously published protocols.\textsuperscript{11, 13} The perovskite precursors (MABr and PbBr$_2$) were dissolved in DMF (ratio 1:1, 0.04 M), together with oleic acid (to avoid the NPs aggregation) and varying amounts of Br NH$_3^+$-C$_{10}$-COOH. A small volume of this solution was injected into toluene under vigorous stirring. The resulting solution was centrifuged in order to remove larger aggregates, and a bright luminescent supernatant suspension was obtained.

By modifying the ligand amount, a strong variation in the optical properties of the suspension was observed. In particular, when a molar ratio of Br NH$_3^+$-C$_{10}$-COOH/MA = 2 was used during the synthesis, a blue light emitting NPs suspension was obtained (Fig. 1a). This dispersion showed a maximum PL emission at 490 nm, FWHM of 22 nm, and PLQY of 25%. The influence of the long chain ammonium ligand Br NH$_3^+$-C$_{10}$-COOH on the color of the resulting suspension is a result of the equilibrium between the formation of three dimensional MAPbBr$_3$ NPs and two dimensional structures where the ligand itself participate in the formation of layered perovskites.\textsuperscript{10, 20-22} In particular, with an excess of Br NH$_3^+$-C$_{10}$-COOH, mainly 2D perovskite nanostructures are obtained. In these materials, the long chain cations alternate inorganic sheets of octahedral lead bromide, resulting in a multi-well, dielectric-semiconductor structure characterized by an increased exciton binding energy.\textsuperscript{20} The formation of such structures leads to an intense and sharp peak in the low energy part of the absorption spectra, as is clearly visible in the case of our suspensions prepared with high ligand content (Fig. 1a). On the other hand, by reducing the amount of ligand used to a molar ratio of Br NH$_3^+$-C$_{10}$-COOH/MABr = 0.5, the typical MAPbBr$_3$ absorption and emission spectra can be observed, as a footprint of 3D NPs formation (Fig. 1b). This dispersion showed narrow and intense photoluminescence (centered at 521 nm, with FWHM of about 20 nm) with an associated PLQY as high as 80%. As mentioned before, the temperature of the non-polar solvent (here toluene) was reported to be of special importance, defining the size and hence the emission wavelength of the NPs.\textsuperscript{11}

![Fig. 1](image1) Absorption (gray) and PL spectra (blue and green) of MAPbBr$_3$ NPs colloidal solutions in toluene for Br NH$_3^+$-C$_{10}$-COOH/MA molar ratio of (a) 2 and (b) 0.5. Insets: photographs of each colloidal solution under UV excitation ($\lambda = 365$ nm).

Interestingly, the synthesis in the presence of Br NH$_3^+$-C$_{10}$-COOH was found to be rather temperature independent. In fact, when the synthesis is carried out at 60 °C, the absorption and luminescence spectra of the obtained NPs suspension are similar to those prepared at room temperature (Fig. S1, ESI).

We investigated the morphology of the NPs suspensions prepared at 25 ºC by transmission electron microscopy (TEM). The electron microscopy confirmed the presence of the perovskite NPs (Fig. 2a) with a diameter in the 3-10 nm range (4.5 nm in average, see Fig. S5 for details). With increased Br NH$_3^+$-C$_{10}$-COOH content, the morphology changes showing wide 2D sheets (50-200 nm) embedding spherical nanocrystals (Fig. 2b). This mixture of nanostructures has been described in several reports, and results from the competition among the formation of 3D and 2D-type perovskites, as described before.\textsuperscript{13, 23} The choice of the cationic ligand Br NH$_3^+$-C$_{10}$-COOH was made in order to enable efficient coordination to the perovskite NPs and, thanks to the carboxyl group, allow for the anchoring of the NPs on functional surfaces, such as metal oxides.\textsuperscript{24} Moreover, the carboxyl group reduces the QD aggregation enhancing the stability of the NPs suspension, in analogy to the function of the oleic acid additive.\textsuperscript{11} Hence, we tested the adhesion of the NPs onto thin films of ZnO, a n-type semiconductor widely used as electron injection layer in OLEDs.\textsuperscript{25} 150 nm thick ZnO layers were prepared by spin-coating and high temperature annealing (400 ºC) of a commercial ZnO NPs suspension, on indium tin oxide (ITO) coated glass substrates. These ZnO coated substrates were immersed into the NPs suspension for 12 hours and then rinsed with toluene before characterization. The ZnO/MAPbBr$_3$ NPs films exhibited bright photoluminescence under UV excitation ($\lambda = 365$ nm) (Fig. 3a, inset), with a maximum PL emission at 514 nm and FWHM of 25 nm (Fig. 3a). Importantly, the associated PLQY of the thin films was as high as 52% when excited at 380 nm. Despite the decrease of the PLQY from dispersion to the solid state, this value is among the highest reported for perovskite NPs thin films, most likely thanks to the anchoring of the NPs which strongly inhibit their aggregation. Time-resolved PL measurements were performed both on the colloidal solution and on the ZnO films functionalized with the NPs (Fig. S4). In accordance with previous reports, the average lifetime for the NPs suspension

was found to be 65 ns, with a long tail extending towards the microsecond timescale. On the other hand, the excited state lifetime was found to be substantially reduced (11 ns) when the MAPbBr₃ NPs were anchored to the ZnO surface. The same effect has been previously observed in MAPbBr₃/TiO₂ bilayers and was ascribed to an efficient electron injection from the perovskite to the metal oxide conduction band. Considering the very similar energy bands alignment of TiO₂ and ZnO, the same mechanism is likely to take place at the MAPbBr₃ NPs/TiO₂ interface, resulting in the shorter excited state lifetime observed here. The efficient charge transfer could also partially explain the PLQY reduction observed for the anchored MAPbBr₃ NPs. Importantly, the ZnO/MAPbBr₃ NPs films maintained their luminescence after washing with toluene, implying that the NPs were effectively anchored to the surface. This is very important since other functional layers (i.e. organic charge transport materials) can be coated on top of the perovskite NPs, allowing for the preparation of multilayer LEDs.

In order to investigate the morphology of the NPs anchored on the ZnO NPs film, atomic force microscopy (AFM) was used. The rather rough ZnO surface (Fig. S2, ESI), however, made it difficult to discern the perovskite NPs. Hence, we looked for a substantially more flat surface compared to the solution processed ZnO that would allow a direct visualization of the perovskite NPs. We selected poly(3,4-ethylenedioxythiophene) doped with poly(styrene sulphonate) (PEDOT:PSS) as a test platform to anchor the MAPbBr₃ NPs. In spite of the very different chemical nature of PEDOT:PSS compared to ZnO, the perovskite NPs did also adhere on the conducting polymer coated substrate, and the films exhibited a maximum PL emission at 513 nm and a PLQY of 50%, analogous to what was observed for the ZnO/NPs systems (Fig. S3, ESI). The adhesion of the perovskite NPs on PEDOT:PSS is most likely promoted by the large amount of ionic groups (and in particular of cationic polythiopene derivatives) present in the conducting polymer, leading to a favorable electrostatic interaction between the carboxyl groups of the ligands and the surface. The morphology of the PEDOT:PSS/NPs thin films were analyzed by AFM. The surface of the PEDOT:PSS film is flat and homogeneous (Fig. 3b), with an associated root-mean-square roughness of only 1.2 nm, calculated over a 2 x 2 μm area. The same surface, when coated with the perovskite NPs, is composed by densely packed particles (Fig. 3c), whose dimensionality can be estimated by measuring the surface profile (Fig. 3d). Structures with height varying from about 5 to 15 nm can be observed, indicating a roughness and hence limited aggregation of the NPs on the surface (considering the particle size distribution obtained from TEM analysis). The lateral size of the particles, as observed from the AFM profiles, appears much larger as it is a deconvolution of the surface and the AFM tip. From this morphological analysis and considering the unchanged optical properties of the NPs when anchored to ZnO or PEDOT:PSS, we conclude that the MAPbBr₃ NPs are grafted on the semiconducting ZnO surface, where they form homogeneous and compact films, suitable for the fabrication of optoelectronic devices. Hence, multilayer LEDs with n-i-p configuration (n-type layer deposited on the transparent substrate) were prepared. The ZnO sensitized with MAPbBr₃ NPs was deposited on ITO coated glass substrates, and a 100 nm thick CBP film (4,4′-Bis(N-carbazolyl)-1,1′-biphenyl, acting as the hole transport layer, HTL) was spin-coated on top from its chlorobenzene solution (20 mg mL⁻¹). The device was finished by vacuum deposition of a thin (10 nm) layer of MoO₃ (facilitating hole injection from the anode to the CBP) and a 100 nm thick gold anode on top. The flat band energy diagram for the materials used in the device is depicted in Fig. 4a.
Fig. 4 (a) Flat band energy diagrams of the materials used in the NPs LEDs. (b) Current density (symbols) and luminance (line) versus applied bias for the same device.

The current density and luminance versus voltage characteristics for a device using MAPbBr$_3$ NPs as the emitting material is reported in Fig. 4b. The current density to voltage behavior shows a typical diode characteristic (low leakage, exponential forward current injection), highlighting the good quality of the device and layers used. The LED turns on at about 1.5 V applied bias, reaching a luminance of 8 cd m$^{-2}$ at 8 V. Unfortunately, the current density at the same applied bias is very high (8 $\times$ 10$^7$ A m$^{-2}$), limiting the overall current efficiency to about 10$^{-3}$ cd A$^{-1}$. This can be a consequence of the extremely thin perovskite NPs layer used (virtually a monolayer), limiting the attainable electroluminescence. An uneven particle distribution causing insufficient coverage could also reduce the overall current efficiency. On the other hand, the ZnO layer used is not completely flat and can hence cause an uneven distribution of the applied field or direct electron-hole recombination at the ZnO surface. It is known that the nanocrystalline morphology of the oxide film plays an important role in determining the electroluminescence process. Considering that indeed LEDs employing a monolayer of luminescent NPs have been demonstrated, a more homogeneous and especially flat surface would be desirable when using MAPbBr$_3$ NPs. Unfortunately, inverted device (p-i-n) employing PEDOT:PSS/MAPbBr$_3$ NPs in combination with an electron transport layer showed no electroluminescence at all. This is not surprising since the PEDOT:PSS/MAPbBr$_3$ is not a blocking interface, and direct charge recombination at the conducting polymer is favored.

In summary, a temperature-independent synthesis of MAPbBr$_3$ nanoparticles (NPs) employing the ammonium salt of 11-aminoundecanoic acid (Br NH$_3$$_3$$_3$$_3$$_3$$_3$$_3$-C$_{10}$-COOH) as ligand has been developed. Dispersions of NPs with a diameter below 10 nm and a PLQY of about 80% can be readily obtained at room-temperature and in atmospheric conditions. Thanks to the use of the Br NH$_3$$_3$$_3$$_3$$_3$$_3$-C$_{10}$-COOH bifunctional ligand, the NPs can be anchored on a variety of electroactive surfaces, such as inorganic semiconductors or conducting polymers. The NPs anchored to ZnO and PEDOT:PSS thin films showed remarkable photoluminescence quantum yield of approximately 50%. The NPs-sensitized ZnO films can be directly integrated into light-emitting devices, leading to modest but homogeneous light-emission. The anchoring of perovskite NPs on several flat and semiconducting surfaces is being investigated, with the potential of opening new paths for the preparation of simple and inexpensive multilayer light-emitting devices.
