This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Highly active hydrogen evolution electrocatalyst based on cobalt-nickel sulfide composite electrode†

Davide Ansovini,a,b Coryl Jing Jun Lee,3 Chiu Sheng Chua,2 Lay Ting Ong,a Hui Ru Tan,a William Webb,b Robert Raja3 and Yee-Fun Lim*a

A novel CoS2-NiS2/Ni foam composite material was synthesized through the thermal decomposition of a cobalt-thiourea molecular precursor onto the 3D metallic support. The obtained electrode exhibited good activity toward the hydrogen evolution reaction in alkaline medium, requiring small overpotential of 163 mV at a current density of 10 mA cm−2, which is one of the lowest ever reported among transition metal sulfides materials.

Recent projections have shown that the world population will increase from 7.2 billion in 2015 to between 9.6 billion and 12.3 billion in 2100.1 Reconciling the energy needs of a large population while mitigating global warming appears to be strictly dependent on renewable energy sources (solar, wind, etc.) and their capacity to be cost-effective and easily scalable for a global and diffuse deployment. One of the principal drawbacks of relying abundantly on renewable energy is represented by its intermittent nature, which does not guarantee a constant electric supply to the grid. In this regard several technologies based on energy storage have been developed, where the energy derived by a renewable source can be stored as thermal,2 electrochemical,3 chemical,4 just to name a few. Among the various existing technologies hydrogen (H2) production through solar-driven water electrolysis has received considerable attention, given the potential key role of hydrogen as a clean fuel and energy carrier.5,6

In order to be commercially viable, electrocatalytic water electrolysis requires active, durable and low-cost electrocatalysts for the hydrogen evolution reaction (HER) and the oxygen evolution reaction (OER). At present, platinum (Pt) and its alloys represent the most efficient catalysts for the HER in both acidic and basic environments, although its high cost and scarcity severely preclude a large-scale use for H2 production.7,8 During the past 10 years numerous efforts have been devoted to the identification of active, stable and low-cost HER electrocatalysts able to efficiently work under harsh (acidic and/or basic) and/or neutral electrolytes. Relevant examples include first-row (Co, Ni, Fe)8–11 and group VI (Mo, W)14–18 transition metal chalcogenides, nitrides,19 phosphides,20–23 group VI transition metal carbides,24,25 borides26 and transition metal alloys.7,27 Particularly, first-row transition metal sulfides such as CoS2,8,10,11,14,19 CoS2P19,20,22 NiS2,28,31 Ni2S3,32 CoS13,35 Ni-S23 have recently emerged as a promising class of active HER electrocatalysts, showing to possess good activity over a broad pH range and reasonable chemical stability under electrocatalytic conditions. Although promising, these materials have not been extensively investigated yet, especially in their behaviour under alkaline media. Indeed, it is highly desirable to find new active and stable HER catalysts operating under alkaline conditions, considering that the most active OER catalysts made of earth-abundant elements are either unstable or inactive under acidic medium.4 They would also be more compatible with existing water electrolysis plants which are usually based on cells with alkaline electrolyte.34

Catalyst nanostructuring onto conductive substrates is an effective synthetic strategy for increasing the surface area, which leads to an improvement of the HER electrocatalytic activity.8,10,11 Moreover, the in situ growth of electrocatalytic materials onto binder-free and three-dimensional (3D) substrates plays a crucial role in obtaining composite electrodes with high mechanical stability and strong interface adhesion.8,15 At present, carbon-based substrates have been mainly investigated, such as reduced graphene oxide,11,18 carbon nanotubes,11,24 carbon paper15 and carbon cloth21 because of their high electronic conductivity, high surface area and inertness. Nickel foam is another substrate of particular interest considering its unique 3D macroporous structure, high electronic conductivity and low cost. Besides, the intrinsic activity of metallic nickel towards the HER under alkaline conditions implies the possibility of designing novel composite electrodes with unprecedented properties.25 Notable examples of HER electrocatalysts supported onto Ni foam include MoS2,15 NiS2,32 NiP3-NiP5,22 Ni-Se nanowires,26 Mo2C.35

† Electronic Supplementary Information (ESI) available: See DOI: 10.1039/x0xx00000x
In this work we report a facile synthetic strategy for the fabrication of a multi-phase cobalt-nickel sulfide HER electrocatalyst supported onto a commercially available Ni foam (Nif). Cobalt and nickel sulfide nanoparticles were generated in situ upon thermal pyrolysis of thiourea, due to the formation of reactive sulfurized molecular species that directly react with the metallic atoms. A detailed investigation on the effect of annealing temperature and time was carried out, establishing a structure-property relation through a combined characterization analyses coupled with HER electrocatalytic tests. The optimum electrode showed a small overpotential of 163 mV required to reach a current density of 10 mA/cm², a Tafel slope of 88 mV/dec and great long-term stability as long as 72 hours.

Our synthetic strategy was inspired by earlier works reporting the formation of pure cobalt sulfide nanoparticles through the thermal annealing under inert atmosphere of a preformed Co-thiourea molecular complex in methanol. In our method the Co-thiourea complex was first adsorbed onto a pre-cleaned Ni foam (Nif) through dip coating, and subsequently annealed under N₂. The metal loading in the electrode can be controlled simply by repeating the two steps of dip coating-annealing (see Experimental details†). We also found that by using only thiourea as a molecular precursor, pure crystalline Ni₅S₈ (heazlewoodite) was formed on the surface of the Nif, whereas in the case of the Co-thiourea precursor, a series of different crystalline phases of nickel sulfides and only one well-defined phase of cobalt sulfide (Co₉S₈) were obtained. Annealing temperature and time were systematically varied (400-500 °C, 10-90 min) for both the monometallic and the bimetallic electrodes, giving precious insights into the structural and morphological transformations involved. Samples obtained by the thermal decomposition of thiourea at a specific temperature (T) and time (t) will be referred as Ni₅S₈/Nif(T,t), whereas those obtained by the thermal decomposition of Co-thiourea complex will be referred as Co₉S₈-Ni₅S₈/Nif(T,t). Unless otherwise stated, all the characterized samples showed below were synthesized by performing 5 cycles of dip coating-annealing.

X-ray diffraction (XRD) patterns for the Ni₅S₈/Nif and the Co₉S₈-Ni₅S₈/Nif electrodes are reported in Fig. S2 and Fig. 1, respectively. In the case of the monometallic system, the XRD patterns show the formation of a pure rhombohedral Ni₅S₈ (JCPDS no. 30-0863) for all the different annealing conditions. No secondary phases were detected. A contrasting behaviour can be observed for the Co₉S₈-Ni₅S₈/Nif electrode, with the formation of a variety of nickel sulfide phases and the cubic Co₉S₈. As we can note from the spectra, the diffraction peaks were carefully indexed by comparing the experimental pattern with reported data, and compounds such as Ni₅S₈ (JCPDS no. 03-0734), Ni₅S₈ (JCPDS no. 76-2306), NiS (JCPDS no. 12-0041), Ni₅S₈ (JCPDS no. 24-1021) and Ni₅S₈ (JCPDS no. 30-0863) were identified. Only one phase of cobalt sulfide was detected, with diffraction peaks indexed to the cubic Co₉S₈ (JCPDS no. 86-2273). Interestingly, the relative presence of each nickel sulfide species depends on the annealing parameters, with sulfur-deficient phases (Ni/S > 1) favoured at high temperature and long annealing time. For instance, the Co₉S₈-Ni₅S₈/Nif(500,90) shows only the presence of Ni₅S₈ (Ni/S = 1.5) along with Co₉S₈, in stark contrast with the multitude of phases observed for the other investigated conditions. The Co₉S₈ phase starts to appear after annealing at 400 °C for 90 min (Fig. 1(b)) and its structural nature does not change with varying the annealing parameters. The presence of Co₉S₈ was further confirmed by Raman spectroscopy as highlighted in Fig. S3, where two peaks located at 510 cm⁻¹ and 1040 cm⁻¹ match well with those reported for the pure Co₉S₈. A broad peak at around 300-350 cm⁻¹ lies in the characteristic range of Ni₅S₈, although its poor resolution hinders a defined deconvolution of the peaks documented in the literature. This could be also due to an overlapping with the other nickel sulfide phases which may have a similar Raman pattern.

The SEM images for the Ni₅S₈/Nif (Fig. S4) and Co₉S₈-Ni₅S₈/Nif (Fig. 2) reveal the formation of a nanoparticulate morphology of similar nature for both electrodes. As a common feature these nanoparticles tend to grow and agglomerate with increasing annealing temperature and time. TEM analysis performed on the Co₉S₈-Ni₅S₈/Nif samples shows the presence of small nanoparticles having a mean diameter of less than 20 nm (Fig. 3).
The atomic percentage of cobalt was determined using energy-dispersive X-ray spectroscopy (EDX) and it was around 4% for all the different electrodes as reported in Fig. S5. A semi-quantitative estimate of the mass loading can be calculated for the CoSy-NiS_x/Nif, giving a value of roughly 2 mg/cm^2 for CoSy and 7 mg/cm^2 for NiS_x (assuming Ni/S = 1.5). In the case of the monometallic NiS_x/Nif electrode, a similar mass loading of 7 mg/cm^2 was obtained (see Fig. S6 for the EDX spectra). Significant amount of carbon and nitrogen was detected as a result of the formation of carbonaceous side products originating from the pyrolytic decomposition of thiourea.

X-ray electron photoelectron spectroscopy (XPS) was performed in order to analyze the chemical composition of the samples and the oxidation state of the elements. The Ni2p, Co2p and S2p XPS spectra of the CoSy-NiS_x/Nif materials are reported in Fig. S7, S8, and S9, respectively. The Ni2p patterns show the presence of a mixed Ni^{2+}/Ni^{2+} oxidation states for the CoSy-NiS_x/Nif(400,10) and CoSy-NiS_x/Nif(500,90), with the typical binding energy of 853.0 eV for Ni^{2+} and 856.0 eV for Ni^{2+}. These values fit well with previous XPS spectra of pure NiS_x, which is a compound with a rich redox chemistry, possessing Ni^{0}, Ni^{2+} and Ni^{3+} species. As suggested by Buckel et al., the Ni2p_{3/2} peak at 856.0 eV can be attributed to the presence of Ni(OH)_2 formed on the surface of the NiS_x upon exposure to atmospheric air.\(^{43}\) This peak is consistently present for all the samples, regardless of the adopted annealing condition. The CoSy-NiS_x/Nif(400,90) and CoSy-NiS_x/Nif(500,10) materials show a slightly different chemistry, with the occurrence of Ni^{3+} species (853.7 eV) derived from nickel sulfide\(^{44}\) and no peaks related to Ni^{0}. The Co2p XPS spectra reveal the presence of Co^{3+} species for all the samples, with a binding energy of 781.0-782.0 eV (Co2p_{3/2}), characteristic of CoS\(^{29}\) Co\^{2+} was detected only for the CoSy-NiS_x/Nif(500,90), with the Co2p_{3/2} peak located at 778.4 eV. This may be due to the partial oxidation of the Co\(^{2+}\) to Co\(^{3+}\) on the surface resulting from the prolonged annealing under relatively high temperature. The S2p XPS spectra are in agreement with the typical binding energies for nickel and cobalt sulfides, with the S2p_{3/2} peak located at 161.4-162.4 eV attributed to a S\(^{2-}\) oxidation state bonded to the metal cation.\(^{29,42}\) In all the samples it is possible to identify another S2p\(_{3/2}\) peak at 168.0-169.0 eV, which is linked to the presence of SO_{3/2}/SO_{2} species on the surface of the metal sulfides resulting from the exposure to air.\(^{41}\) A detailed quantitative analysis of the XPS derived from the fitting of the experimental spectra can be found in Table S1. The results show that the Co/Ni atomic ratio is 1.2, 1.0, 0.5 and 3.3 for the CoSy-NiS_x/Nif(400,10), CoSy-NiS_x/Nif(500,90), CoSy-NiS_x/Nif(500,10) and CoSy-NiS_x/Nif(500,90), respectively. Furthermore, the S/(Co+Ni) ratio is lower for the electrodes treated at 500°C, which is in line with the structural modifications observed by XRD, with sulfur-poor nickel sulfide phases favoured at high temperature. The Ni2p and S2p XPS spectra of the monometallic NiS_x/Nif electrode displayed in Fig. S10 fit with the patterns reported in the literature for pure NiS_x.\(^{42}\)

The HER activity of the CoSy-NiS_x/Nif and NiS_x/Nif electrodes was evaluated through linear sweep voltammetry in 1M KOH aqueous electrolyte and the correspondent polarization curves after iR correction are displayed in Fig. 4(a) and (b), respectively. As we can observe in Table 1, the HER activity of the CoSy-NiS_x/Nif is superior compared to the monometallic NiS_x/Nif electrode. The CoSy-NiS_x/Nif(500,10) electrode showed the best performance with a required small overpotential of 163 mV to reach a current density of 10 mA/cm^2, typical figure of merit used for comparing the activity of electrocatalysts in a hypothetical solar-driven electrochemical water splitting device operating at 12.3% efficiency.\(^{41}\) This value compares well with the best reported earth-abundant metal HER electrocatalysts under alkaline media, and a quantitative comparison in terms of HER performance can be found in Table S2. For the CoSy-NiS_x/Nif sample, the HER activity trend is correlated with the specific annealing conditions. The CoSy-NiS_x/Nif(500,90) electrode showed a dramatic drop in activity compared to the other ones, with an overall performance even worse than the bare Ni foam. This difference can also be seen in the value of the Tafel slopes, which is an indication of the mechanistic reaction pathway. Similar values ranging from 83 to 91 mV/dec were found for the active CoSy-NiS_x/Nif(400,10), CoSy-NiS_x/Nif(400,90) and CoSy-NiS_x/Nif(500,10), suggesting a mixed Volmer-Heyrovsky rate-determining step (RDS) occurring on these electrodes. In stark contrast, the Tafel slope of the CoSy-NiS_x/Nif(500,90) electrode is 117 mV/dec, quite close to the value

---

**Fig. 3** TEM images for CoSy-NiS_x/Nif at different annealing temperatures and times (a) 400 °C 10 min, (b) 400°C 90 min; (c) 500°C 10 min, (d) 500°C 90 min. Selected area electron diffraction patterns for CoSy-NiS_x/Nif at (e) 500°C 10 min and (f) 500°C 90 min.
obtained for the bare Ni foam, typical of a pure Volmer RDS. The much lower activity of the Co$_9$S$_8$-Ni$_2$S$_3$/Nif(500,90) sample can be ascribed to the different structural, compositional and morphological properties. In particular, three factors appear to be significantly different from the more active bimetallic electrodes: i) higher Co/Ni superficial atomic ratio, ii) absence of other nickel sulfides phases apart from Ni$_2$S$_3$, iii) nanoparticulate agglomeration. A higher Co/Ni atomic ratio means that more Co$_9$S$_8$ particles are exposed to the electrolyte compared to Ni$_2$S$_3$, and this can explain the mechanistic difference existing for the Co$_9$S$_8$-Ni$_2$S$_3$/Nif(500,90) sample. Indeed, the Tafel slopes of the monometallic Ni$_2$S$_3$/Nif lie in the range 87-106 mV/dec (Table 1), similar to the values obtained for the Co$_9$S$_8$-Ni$_2$S$_3$/Nif(400,10), Co$_9$S$_8$-Ni$_2$S$_3$/Nif(400,90) and Co$_9$S$_8$-Ni$_2$S$_3$/Nif(500,10) materials. This suggests that Ni$_2$S$_3$ plays an active role in the mechanistic pathway of the HER, perhaps having a more favourable adsorption capacity of water molecules compared to Co$_9$S$_8$. Recently, Feng et al. showed a rather poor HER activity of Co$_9$S$_8$ in alkaline media, with a required overpotential of 250 mV to reach a current density of 10 mA/cm$^2$.[10] This value is in agreement with the performance of the Co$_9$S$_8$-Ni$_2$S$_3$/Nif(500,90), leading to the conclusion that pure Co$_9$S$_8$ is not a particularly active catalyst for the HER. However it is worth noting that even the pure Ni$_2$S$_3$/Nif has a much lower activity compared to the active bimetallic electrodes. The best material showed a modest overpotential of 225 mV in order to reach 10 mA/cm$^2$, only 20 mV lower than the bare Ni foam. In this regard, we propose the presence of a synergistic effect between Co$_9$S$_8$ and Ni$_2$S$_3$ as the main reason why we observe a dramatic improvement in the HER activity of the Co$_9$S$_8$-Ni$_2$S$_3$/Nif under well-defined synthetic conditions. This effect arises from an intimate contact of the two phases and an appropriate atomic composition on the surface of the electrode. Such synergistic effects had also been previously observed in Ni-Co alloys for hydrogen evolution, which were found to be superior to pure Ni or pure Co catalysts.[26]

Our hypothesis was also supported by electrochemical impedance spectroscopy (EIS) measurements, which further unveiled the main differences in the electrochemical properties of the mono and bimetallic catalysts. The Nyquist plots for the Co$_9$S$_8$-Ni$_2$S$_3$/Nif and Ni$_2$S$_3$/Nif are reported in Fig. S12 and were fitted using a Randles circuit, consisting of a series resistance ($R_s$), a charge transfer resistance ($R_{ct}$) and a constant phase element (CPE). The $R_{ct}$ gives a measure of the ease of electron transfer at the electrode/electrolyte interface.[11] As reported in Tab. 1, this value is lower for the Co$_9$S$_8$-Ni$_2$S$_3$/Nif compared to Ni$_2$S$_3$/Nif, although this is not true for the less active Co$_9$S$_8$-Ni$_2$S$_3$/Nif(500,90) sample, having a similar value to the monometallic system. Another relevant parameter is the double-layer capacitance ($C_{dl}$), which is derived from the CPE data. The $C_{dl}$ is an important figure of merit since it gives an estimate of the electrochemically active surface area (ECSA).[17] The calculated $C_{dl}$ of the active Co$_9$S$_8$-Ni$_2$S$_3$/Nif electrodes is much higher than the Ni$_2$S$_3$/Nif (Table 1), with values ranging from 44 to 64 mF/cm$^2$, in agreement with their superior HER activity. Again, the $C_{dl}$ of the poorly active Co$_9$S$_8$-Ni$_2$S$_3$/Nif(500,90) sample is significantly lower and comparable to the monometallic Ni$_2$S$_3$/Nif. The enhanced electrochemically active area of the Co$_9$S$_8$-Ni$_2$S$_3$/Nif electrodes synthesized under appropriate conditions is a direct evidence of the existence of more active sites, which are linked to the particular compositional and electronic configuration at the surface. Also, the intrinsic metallic nature of the Co$_9$S$_8$ and Ni$_2$S$_3$ phases favours the rapid electron transfer at the electrode/electrolyte interface.

In our discussion we treat Ni$_2$S$_3$ as the only active nickel sulfide phase in the system, without taking into account the possible effect of other phases. However this can be justified by two main observations: i) XRD, SAED and XPS gave evidence of a predominant presence of the Ni$_2$S$_3$ and Ni$_2$S$_3$$\alpha$ phases; ii) XRD analysis after the stability test evidenced the disappearance of the Ni$_2$S$_3$$\alpha$ phase (Fig. 5).

**Table 1** Summary of the electrochemical properties of the Co$_9$S$_8$-Ni$_2$S$_3$/Nif and Ni$_2$S$_3$/Nif electrodes for the HER in 1M KOH.
S(b)), despite the fact that no current decay was observed after 72 hours for the most active sample (Co$_{8}$S$_{7}$-Ni$_{17}$/Nif(500,10)), as shown in Fig. 5(a). This leads to the conclusion that the active sites are due to the biphase Co$_{8}$S$_{7}$-Ni$_{17}$/S$_{2}$ system, which is also perfectly retained after chronoaeropometric test as shown by XRD, resulting in a stable and constant current density throughout the experiment. Furthermore, the Co$_{2}$p and Ni$_{2}$p XPS patterns reported in Fig. S10 match those of the as-synthesized sample, with a similar Co/Ni superflcial atomic ratio calculated from the fttng of the XPS spectra (Table S2). The nanoparticulate morphology of the Co$_{8}$S$_{7}$-Ni$_{17}$/S$_{2}$/Nif(500,10) is retained after long-term stablity, as shown by the low- and high magnification SEM images in Fig. 5 (c). Only minor modiﬁcations occurred, most likely due to the dissolution of the unstable Ni$_{17}$/S$_{2}$ phase. No cobalt leaching was observed as probed by EDX technique and summarized in the chart reported in Fig. 5 (d), with a value consistent with the as-synthesized sample.

**Conclusions**

We have developed a novel and facile synthetic method for the fabrication of bimetallic Co$_{8}$S$_{7}$-Ni$_{17}$/S$_{2}$ nanoparticles supported onto a 3D Ni foam. The method is based on the thermal decomposition of pre-adsorbed molecular precursors onto the metallic Ni foam, generating in situ the nanoparticulate metal sulfi-des. The bimetallic Co$_{8}$S$_{7}$-Ni$_{17}$/S$_{2}$/Nif electrodes showed a signiﬁcantly higher activity compared to the nanoparticulate metal sulfides. The bimetallic Co$_{8}$S$_{7}$-Ni$_{17}$/S$_{2}$/Nif for the hydrogen evolution reaction, with the Co$_{8}$S$_{7}$-Ni$_{17}$/S$_{2}$/Nif(500,10) sample requiring a small overpotential of 163 mV at a current density of 10 mA cm$^{-2}$ in 1M KOH electrolyte. Synthetic parameters such as annealing temperature and time were found to play a crucial role in the HER activity, establishing a structure-property correlation through a detailed characterization analysis. The origin of the high activity of the Co$_{8}$S$_{7}$-Ni$_{17}$/S$_{2}$/Nif synthesized under well-deﬁned conditions was attributed to the existence of a synergistic effect between Co$_{8}$S$_{7}$ and Ni$_{17}$/S$_{2}$ nanoparticles. This effect arises from an optimal atomic composition at the surface and an intimate contact between the two nanoparticulate phases, having a small size of 20 nm. The analysis of the Tafel slopes for the active Co$_{8}$S$_{7}$-Ni$_{17}$/S$_{2}$/Nif reveal a mixed Heyrovsky-Volmer mechanism occurring during the HER. It has been shown that the adsorption of reacting water molecules on the active sites is largely favoured by the Ni$_{17}$/S$_{2}$ phase. The HER trend was also correlated to the electrochemical properties of the electrodes such as double layer capacitance and charge transfer resistance. Consistent results were found, with the active bimetallic Co$_{8}$S$_{7}$-Ni$_{17}$/S$_{2}$/Nif samples having the largest ECSA and smallest $R_{ct}$. The most active Co$_{8}$S$_{7}$-Ni$_{17}$/S$_{2}$/Nif(500,10) electrode was subject to chronoaeropometry test, and great long-term stablity was observed, with a constant current density maintained over 72 hours of reaction. The Co$_{8}$S$_{7}$ and Ni$_{17}$/S$_{2}$ phases were perfectly retained after the test, as evidenced by XRD, SEM, XPS and EDX analyses. Only small morphological and structural modiﬁcations were recored as a result of the dissolution of the unstable Ni$_{17}$/S$_{2}$ phase. Our new synthetic approach can be easily generalized and extended to the design of others 3D composite materials holding novel and unprecedented properties in a broad variety of applications such as HER/OER catalysts, supercapacitors and batteries.
