used in biosensingLei Zhang,^{†a} Yanbing Yang,^{id} ^{†a} Jie Tan,^{id} ^{*a} and Quan Yuan,^{id} ^{*ab}

Biopolymers are highly designable and are often used in biosensing processes. As a biopolymer, a nucleic acid not only has excellent programmability and biocompatibility, but also has a certain molecular recognition function that can directly realize biological recognition in biosensors. However, the structural variety of natural nucleotides hinders the designability of nucleic acid biopolymers. The introduction of chemical modifications in nucleic acids can enrich the designability of nucleic acid biopolymers, thereby expanding their applications in biosensing. To date, there have been many reviews paying attention to biopolymers used in biosensing, but few reviews have focused on chemically modified nucleic acid biopolymers. Here, we review different kinds of assemblies based on chemically modified nucleic acid biopolymers. We summarize their advances in the field of biosensing. Furthermore, we present challenges and prospects in this field, aiming to provide a promising step for a versatile biosensor platform based on chemically modified nucleic acid biopolymers.

1. Introduction

Biosensing consists of a biorecognition process and a transduction process.^{1–4} Due to their high designability, biopolymers are often used to connect the biorecognition process with the transduction process.^{5,6} It is worth noting that biopolymers can form

nanostructures through a highly controllable dynamic assembly process, enabling the application of biosensing at the cellular or *in vivo* level.^{7–10}

A nucleic acid, as a biopolymer, has excellent programmability and biocompatibility.^{11–16} In addition, nucleic acids with specific sequences can show a molecular recognition function and can be directly used in the biological recognition process.^{17,18}

However, the structural variety of natural nucleotide hinders the designability of nucleic acid biopolymers, thereby limiting their applications in biosensing.^{12,19} The introduction of chemical modifications can enrich the functional groups of nucleic acids and enhance the intermolecular interactions between nucleic acids.^{20–22} Thus, chemically modified nucleic acids enable the design of nucleic acid biopolymers.^{23,24} Therefore, chemically

modified nucleic acid biopolymers hold great promise in the field of biosensing.^{25,26}

To date, there have been many reviews on biopolymers used in biosensing,^{27–31} but few reviews have paid attention to chemically modified nucleic acid biopolymers. In this review, we focus on chemically modified nucleic acid biopolymers and their applications in biosensing. Specifically, we introduce the assembly methods of chemically modified nucleic acid biopolymers and the applications in biomolecule detection, controlled drug release, and gene therapy. Finally, the challenges and prospects in this field are also comprehensively discussed, aiming to provide a promising step for a versatile biosensor platform based on chemically modified nucleic acid biopolymers.

2. Assembly of chemically modified nucleic acid biopolymers

Nanoassemblies are often used in biosensing due to their similar size to biomolecules.^{32,33} Studies have shown that the design of nanostructures in two and three dimensions can greatly increase the sensitivity of biomolecule-targeted biosensors.^{34,35} Besides complementary base pairing interactions, chemical modifications can introduce new molecular interactions in nucleic acids.³⁶ The new molecular forces enable the design of various geometric structures and bionic structures, creating opportunities for biosensing applications.^{21,37} In the following section, we mainly introduce assemblies based on chemically modified nucleic acid biopolymers with three assembly methods: complementary base pairing-mediated crosslinking method, hydrophilic–hydrophobic interaction-mediated crosslinking method, and metal ion-associated crosslinking method.

2.1 Complementary base pairing-mediated crosslinking method

It has been found that complementary base pairing is one of the major driving forces in DNA self-assembly processes.^{38–40} Previous research studies have shown that nucleic acids can be assembled into DNA nanostructures with controllable size and shape *via* complementary base pairing.^{41–45} The same goes for

Fig. 1 Schematic diagram of two-dimensional nanosheet assembly. Reproduced with permission from ref. 47. Copyright 2019, American Chemical Society.

chemically modified nucleic acids, which could develop several nanostructures *via* base pairing interactions: nanosheets, hydrogels, tetrahedra, nanotubes, and nanoflowers.

DNA origami can be used as a carrier to load various components to expand its application.⁴⁶ Very recently, Zhao *et al.* established a delivery platform based on DNA origami nanotechnology, which can transport payloads effectively for tumor treatment.⁴⁷ They used a long M13mp 18 genomic DNA single strand as a scaffold, mixed with multiple pre-designed staple strands and capture strands. These strands were annealed to fold into rectangular DNA origami nanosheets. The size of nanosheets is about 90 nm × 60 nm × 2 nm. The complementary strands on the cytotoxic protein ribonuclease (RNase) A molecules were hybridized with capture strands to generate protein–DNA conjugates (Fig. 1). The nanosheets then transported RNase into the cells to exert the cytotoxicity function. To target cancer cells, the authors used aptamers as a guide. Aptamers are oligonucleotides with high affinity and selectivity for targets, which are obtained from *in vitro* screening.⁴⁸ The aptamers targeting mucin 1 (MUC1) on a human breast adenocarcinoma cell line were integrated into the nanosheets, which significantly improved the effect of cancer treatment. Similarly, Chen *et al.* mixed an M13mp 18 single-strand DNA (ssDNA), tiles, and probes together to self-assemble into rectangular nanosheets.⁴⁹ Subsequently, they used the nanosheets as a template, and precise assembly of proteases and corresponding coenzymes can be achieved. DNA origami nanostructures can precisely control the horizontal distance between enzymes so as to regulate the catalytic activity of the enzyme cascade. Zhou *et al.* used a similar method to prepare triangular nanosheets with a complete cavity, and the side length of the cavity was about 50 nm.⁵⁰ These studies show

Jie Tan earned her PhD degree from Zhejiang University in 2016. Then she joined the team of professor Weihong Tan at Hunan University as a postdoctoral fellow. Currently, she is an associate professor at Hunan University. Her main research interest is the design of chemically modified nucleic acids for biosensing.

Quan Yuan

Quan Yuan received her BS degree from Wuhan University and PhD degree from Peking University. Afterwards, she worked as a postdoctoral researcher in the group of professor Weihong Tan at the University of Florida. Currently, she is a professor at Hunan University. Her research interests are the construction of nucleic acid nanomaterials and related biomedical applications.

that the framework design guided by DNA hybridization enables the fabrication of nanosheets of different shapes.

In addition to 2D origami nanosheets, it has been widely reported that a well-defined DNA hydrogel can be constructed through rational design and precise synthesis of DNA strands.^{51–53} As a case in point, rapid *in situ* formation of polypeptide-DNA hydrogels was reported by Li *et al.*⁵⁴ First, DNA-grafted polypeptides were prepared by an azide-alkyne click chemistry reaction. Five to six ssDNA motifs were conjugated to the backbone of each peptide, ensuring sufficient crosslinking sites. Additionally, double-stranded DNA served as a DNA linker containing two “sticky ends” that have the same sequence complementary to the DNA motifs. As a consequence of mixing DNA-grafted polypeptides and DNA linkers in a buffer solution, the fluidic solution changed to a transparent supramolecular crosslinking network within a few seconds (Fig. 2a). Tests showed that the mechanical strength of the chemically modified hydrogel was significantly enhanced. In another study, Li *et al.* also synthesized multifunctional supramolecular hydrogels by DNA-grafted polypeptides.⁵⁵ The difference is that they used an “X”-shaped DNA as a crosslinker instead of the linear DNA linker. The “X” shaped DNA strands are divided into two parts; one part is used as crosslinking sites, and the other part could be used for further functional modification. Subsequently, the two crosslinking sites are linked to the DNA-grafted polypeptide through precise base pairing to form a hydrogel structure (Fig. 2b). By this method, the resultant hydrogel can integrate various functional molecules to achieve applications in the biomedical field.

Three-dimensional DNA tetrahedral nanostructures have been widely studied because of their excellent mechanical stiffness and structural stability.^{56,57} Pei *et al.* did an elegant

Fig. 2 Hydrogel assembly with linear (a) and X-shaped (b) DNA linkers. Figures reproduced with permission from: a, ref. 54. Copyright 2015, Wiley-VCH; b, ref. 55. Copyright 2014, Wiley-VCH.

work on the design of DNA tetrahedral nanostructures. They designed four ssDNAs with complementary sequences.⁵⁸ Among them, three single chains are modified with the thiol group, and the other side chain contains a DNA probe. Four chains are mixed in an equivalent stoichiometric ratio, and the DNA tetrahedron is generated by annealing (heating, then rapid cooling) (Fig. 3a). This assembly process was fast (within two minutes) and the yield was high. This assembly method provides a new idea for constructing DNA tetrahedral probes with ordered orientation, controlled spacing and high stability. Besides, Li *et al.* assembled a DNA tetrahedron, which was constructed by three carboxyl group modified DNA strands (55 nucleotides) and a DNA strand containing an aptamer sequence (87 nucleotides).⁵⁹ Four ssDNAs were quickly assembled into a tetrahedron with an edge length of 5.8 nm and each edge was an 18 base pair double helix (Fig. 3b). Polyacrylamide gel electrophoresis (PAGE) results showed that the DNA strands effectively self-assembled in the designed direction (Fig. 3c). The tetrahedral structure keeps the distance distribution of each chain the same, thereby reducing the spatial effect and improving the stability and recognition ability of biomolecules.

Apart from these structures, chemically modified nucleic acids can be assembled into tubular structures by complementary base pairing. According to the previous ssDNA tile assembly method,⁶⁰ Kocabey *et al.* designed 24 functional oligonucleotides; after over 17 hours of annealing, the oligonucleotides were finally assembled into small tubular nanostructures with excellent stability (Fig. 4).⁶¹

In addition to the aforementioned DNA nanoassemblies, Zhang *et al.* synthesized submicron-scale DNA nanoflowers.⁶² A closed circular DNA containing the complementary sequences of aptamer Sgc8 was used as a template, and Sgc8 tandem repeat DNA sequences were generated by base pairing. The final long DNA sequence can spontaneously form nanoflower structures through crystallization, nucleation and growth processes. Finally, the authors introduced the DNA strands incorporating ferrocene (Fc)

bases into the nanoflower (Fig. 5). The research indicated that the size of nanoflowers can be effectively adjusted by the introduction of Fc bases.

2.2 Hydrophilic–hydrophobic interaction-mediated crosslinking method

Similar to the assembly of amphiphilic polymers, the hydrophilic–hydrophobic interaction also plays a relevant role in the assembly processes of nucleic acid biopolymers.⁶³ By modifying with hydrophobic groups, hydrophilic nucleic acids can turn into amphiphilic biopolymers, forming different structures through hydrophilic–hydrophobic interactions.^{64–67} Additionally, assemblies of specific size and shape can be obtained by changing the ratio of hydrophilic to hydrophobic chain length.^{65,68,69} In this section, we will introduce chemically modified nucleic acid assemblies formed *via* hydrophilic–hydrophobic interactions.

Linking hydrophobic units to hydrophilic units through covalent interactions is the main way to construct amphiphilic motifs.^{70–72} Liu *et al.* connected hydrophilic DNA strands to hydrophobic diacyl lipids to form DNA–lipid molecules (Fig. 6a).⁷³ They analysed the effect of DNA strand length on micelles. Atomic force microscopy (AFM) and dynamic light scattering (DLS) results showed that fine-tuning the length of the DNA sequence can achieve the purpose of adjusting the size of the micelles (Fig. 6b and c). In a similar study, Wu *et al.* linked diacyl lipids to nucleic acid aptamers *via* polyethylene glycol to assemble a highly ordered micelle-like structure.⁷⁴ In this structure, the nucleic acid strand

Fig. 6 (a) Illustration of assembly of diacyl-DNA micelles. AFM (b) and DLS (c) characterization of DNA micelles. Reproduced with permission from ref. 73. Copyright 2010, Wiley-VCH.

not only serves as the basis of the nanostructure but also performs a recognition function for a specific target. These aptamer–lipid assemblies enhance the binding ability to the target in a complex biological environment.

Inspired by the higher hydrophobicity, lower solubility, and stronger aggregation tendency of fluorocarbon groups, Zou *et al.* replaced the traditional diacyl chain with a fluorocarbon chain to construct micelles (Fig. 7).⁷⁵ Micelles formed by chain amphiphilic polymers have higher stability, and the critical micelle concentration values are significantly reduced. Thus, creating new hydrophobic building units enables the formation of amphiphilic biomolecules with different properties and expands the versatility of nanomicelles.

Moreover, adding chemically modified nucleotides is another way to introduce hydrophobic groups into hydrophilic nucleic acid chains.^{76,77} Kimoto *et al.* used the unnatural base 7-(2-thienyl)-imidazo[4,5-*b*]pyridine (Ds) as the hydrophobic moiety in the aptamer selection process.⁷⁸ In their research, the addition of Ds bases not only improved the performance of aptamers, but also successfully introduced hydrophobicity into the DNA strands. Tan *et al.* integrated hydrophobic ferrocenes into hydrophilic DNA strands using a similar method and constructed aptamer–ferrocene assemblies (ApFAs) based on hydrophilic–hydrophobic interactions.⁶⁸ Ferrocene bases are prepared by the reaction of (*S*)-3-amino-1,2-propanediol and ferrocene carboxylic acid. Then using

standard phosphoramidite chemistry, the chemically modified nucleic acids are synthesized on the DNA synthesizer by linking ferrocenes to natural bases. By designing synthetic procedures, the authors can synthesize oligonucleotides with specific bases at specific positions. The purified and desalted products can be assembled into micelles after being placed in the DPBS buffer for a certain time. Among them, the hydrophilic nucleic acid fragment is located on the surface of the assemblies in the form of a corona, and the hydrophobic ferrocene fragment forms the core (Fig. 8a). By regulating the number of hydrophobic ferrocene nucleotides, micelles of different sizes can be synthesized. Transmission electron microscopy (TEM) and DLS results showed that as the number of ferrocene nucleotide groups increased, the size of ApFAs increased gradually (Fig. 8b).

2.3 Metal ion-associated crosslinking method

Metal ions have aroused wide interest in biosensing since they play critical roles in biological organisms.^{79–82} Recently, nucleic acids have also been developed to form nanostructures with the assistance of metal ions.^{83,84}

Lyu *et al.* designed a method for DNA micelle crosslinking *in situ* with the assistance of metal ions.⁸⁵ The monomer that makes up the micelle is formed by the covalent attachment of a single stranded DNA and a hydrophobic diacyl lipid. Specifically, the monomer consists of three parts, the most important of which is the part that acts as a template chain (Fig. 9a). The template chain with specific sequences can adsorb different metal ions. The authors selected Cu^{2+} , Ag^+ , and Au^{3+} to prepare different DNA micelles. Subsequently, the metal ions were reduced to zero-valent metals, which can be crosslinked into hollow or solid metal nuclei, thereby promoting the crosslinking of DNA micelles (Fig. 9b). In addition to the single-stranded micelles based on diacyl lipids, two cholesterol-modified double-stranded DNAs (dsDNAs) can also act as template domains. The authors have verified this. Compared with the single cholesterol-modified chain, the strong hydrophobic force produced by the two cholesterol-modified dsDNA

Fig. 9 (a) Monomer structure consisting of three domains. (b) Metal ion-assisted crosslinking process of DNA micelles. Reproduced with permission from ref. 85. Copyright 2019, Elsevier.

can stabilize the micelle structure. Using CuSO_4 as a copper source and L-ascorbic acid as a reducing agent, it was found that cholesterol-modified dsDNA promoted micelle crosslinking, which can be demonstrated by fluorescence intensity and TEM characterization.

Inspired by the unique structures of the DNA G-quadruplexes,⁸⁶ Lu *et al.* proposed that in the presence of K^+ ions, the crosslinking effect of G-quadruplexes was used to promote the formation of hydrogels.⁸⁷ Acrydite-modified oligonucleotides are polymerized with acrylamide monomers to form copolymer chains under the catalysis of initiators. After adding K^+ ions, G-rich nucleic acid sequences self-assemble into G-quadruplex structures, so that polyacrylamide chains are cross-linked to form a DNA hydrogel (Fig. 10). To verify the role of K^+ in gel formation, the authors added crown ether that can capture K^+ ions, then the crosslinked G-quadruplex broke down, and the DNA hydrogel became a solution. Based on the fact that K^+ can stabilize the structure of G-quadruplex, Jin *et al.* designed a DNA sequence rich in G bases and developed a technique to stabilize the DNA micelle structure.⁸⁸ With the addition of K^+ , adjacent guanine bases in the micellar canopy formed G-quadruplexes *via* Hoogsteen hydrogen bonding, and the hydrophobic lipid tails are confined within the micellar nucleus, thereby stabilizing the structure of

Fig. 11 Schematic illustration of the M²⁺-assisted reversible assembly of SNAs.

micelles. These results showed that K⁺ can promote the assembly of the gel and achieve reversible switching.

Unlike the works described above, the work by Joo *et al.* was based on the basic interaction between natural nucleobases and metal ions (M²⁺s) without any pre-designed DNA sequence.⁸⁹ In other words, even if the nucleic acid sequence of SNAs doesn't meet the requirements of complementary base pairing, it can induce the assembly of single-type spherical nucleic acids (SNAs). Taking Cu²⁺ as an example, a spherical nucleic acid solution with gold nanoparticles as the core was reacted with different concentrations of Cu²⁺ for 12 h. As the concentration of Cu²⁺ increases, SNAs form larger aggregates. Furthermore, as the crosslinking reaction occurs, changes in the color of the solution can be observed with the naked eye, indicating the formation of assemblies. This research has shown that M²⁺s can coordinate with multiple bases of SNAs through coordinative interactions, thereby crosslinking into large aggregates (Fig. 11). Once M²⁺s are chelated by a stronger ligand, the assembled SNAs can be dissociated immediately. These studies showed that metal ions can mediate the formation of assemblies and can be reversibly reduced by removing metal ions.

3. Application in biosensing

Recently, much work has integrated biological functions into biosensing to achieve biomedical functions with high sensitivity and specificity.^{90–92} This requires that the materials used in biosensing can interact with and respond to target signals uniquely. Nucleic acid biopolymers show recognition ability to target molecules with good selectivity.⁹³ The addition of chemical modifications can impart new chemical properties and biological functions to nucleic acid biopolymers.^{94,95} Therefore, the chemically modified nucleic acid biopolymers hold great potential to realize multifunctional biosensing. In this section, we will introduce the applications of chemically modified nucleic acid biopolymers in three parts: biomolecule detection, controlled drug release, and gene therapy.

3.1 Detection of biomolecules

The detection of biomolecules can provide us with a lot of information, which will help us make more accurate judgments

on various life processes.^{96–98} Nucleic acids with specific sequences have the potential to recognize targets.⁹⁹ However, the biological environment is so complicated that it limits the use of nucleic acid biopolymers in target recognition.¹⁰⁰ Chemically modified nucleic acid biopolymers enable the specific and sensitive detection of targets. Here, we highlight the application of chemically modified nucleic acid biopolymers in biomolecule detection.

As exosomes are one of the biomolecules for early diagnosis of cancer, it is of great significance to detect exosomes with high sensitivity.^{101–103} Wang *et al.* fixed a nanotetrahedron (NTH) on the gold electrode and designed an aptamer-based biosensor (aptasensor) for detecting hepatocyte exosomes (Fig. 12a).¹⁰⁴ When the sensor is incubated with the exosome suspension, the aptamer on the NTH binds to the exosomes specifically. The binding of the aptamer and exosome reduces the electrode surface area, which causes changes in electrical signals. Accordingly, changes in the electrical signal reflect the concentration of exosomes. Compared with the single-chain aptamer functionalized aptasensor, the detection sensitivity of the NTH-assisted aptasensor is increased by about 100 times (Fig. 12b).

In another study, Wu *et al.* constructed switchable aptamer micelle flares (SAMFs) for the detection of ATP molecules.¹⁰⁵ The SAMF hydrophobic diacyl lipid tail is linked to a hydrophilic switchable aptamer head (Fig. 13a). When there are no targets, the aptamer probe retains the loop-stem structure, causing the fluorescence of the fluorophore to be quenched by an adjacent quencher. After binding to the target, the conformation of the aptamer changes and the fluorescence signal is restored. Based on this principle, a series of different concentrations of ATP are used to measure the response of SAMFs. It is observed that as the ATP concentration increases, the fluorescence signal intensity increases firstly and then reaches saturation (Fig. 13b). The lack of the target ATP prevents the stem-loop structure from opening, resulting in a lower fluorescence signal intensity. When the ATP molecules are added at 75 seconds, the fluorescence signal shows a straight upward trend and the response speed is fast (Fig. 13c). This study demonstrated that SAMFs can respond to ATP expression sensitively and detect ATP molecules through changes in fluorescent signals.

The detection of mRNA is of great significance for early tumor screening.¹⁰⁶ Existing methods for detecting mRNA in cells have many limitations; for example, the probe is susceptible to interference by complex cellular environments, or the stability of the probe is poor.¹⁰³ He *et al.* constructed a DNA tetrahedron

Fig. 12 (a) Illustration of the NTH-assisted aptasensor. (b) Comparison of signals between single-chain aptamer-assisted and NTH-assisted sensors. Reproduced with permission from ref. 104. Copyright 2017, American Chemical Society.

Fig. 13 (a) Structure of SAMFs and their working principle. (b) Relationship between the ATP concentration and fluorescent signal. (c) Effect of adding target molecules on fluorescence intensity. Reproduced with permission from ref. 105. Copyright 2013, American Chemical Society.

nanotweezer (DTNT) to solve the above problems.¹⁰⁷ To be specific, the DTNT completed the mRNA detection with high sensitivity and high accuracy *via* the principle of fluorescence resonance energy transfer. They customized four DNA strands, two of which modified the Cy3 or Cy5 fluorophore respectively. In the absence of targets, the two fluorophores in the DTNT are far away, and the FRET is in the “off” state. When the target mRNA exists in the cell, the two fluorophores are located close to each other, which induces the generation of FRET and the signal changes from “off” to “on”.

3.2 Controlled drug release

In recent years, the applications of smart drug delivery systems in the field of biosensing have been widely studied.^{108–111} Chemically modified nucleic acid biopolymers can also be used to construct smart drug delivery systems.^{112–114}

A DNA origami structure is often used as a drug carrier system due to its excellent biocompatibility and spatially addressable functions.^{41,115} Jiang *et al.* inserted anticancer drug doxorubicin (DOX) into DNA origami nanostructures through non-covalent bonding to reach a high level of drug loading efficiency.¹¹⁶ The DNA origami structure was effectively internalized into cells and remained in the tumor area for a long time. When the drug-loaded origami is exposed to low environmental pH or DNase, DNA nanostructures are slowly degraded to achieve controlled drug release (Fig. 14). Therefore, using DNA origami to carry drugs greatly improves the internalization ability of DOX, which will help the drug to exert its effect and kill tumor cells. In addition, the amphiphilic block copolymer can form a hydrophilic corona and a lipophilic core, and the core can be effectively loaded with hydrophobic anticancer drugs. Based on this, Alemdaroglu *et al.* assembled DNA-polypropylene oxide (PPO) into a spherical micelle structure.¹¹⁷ Dox is a hydrophobic drug, and due to the hydrophobic interaction

Fig. 14 DNA origami-based controlled drug release system. Reproduced with permission from ref. 116. Copyright 2012, American Chemical Society.

of Dox and PPO, drugs accumulate inside the micelles to form a drug delivery system.

Mitochondria play an important regulatory role in tumor growth. Jiang *et al.* developed a mitochondria-specific DNAtain (MitoDNAts) drug delivery system using DNA as the basic unit (Fig. 15).¹¹⁸ The indocyanine dye Cy5.5 is used to provide the driving force, while the linear DNA strand is used as a carrier for transporting a good deal of anticancer drugs. Guided by Cy5.5, drugs are targeted to the mitochondrial region. The release of the drugs can be detected because Cy5.5 has a visualizable fluorescent signal. Applying MitoDNAts to breast cancer cells, and comparing the intracellular fluorescence signals at different times, it is clear that the intracellular fluorescence signals gradually increase. The results mean that drugs are gradually released from MitoDNAts, and the imaging method can be used to visualize the drug release process in time. Additionally, Li *et al.* also designed a controlled drug release system.¹¹⁹ They coupled a nucleolin-targeting aptamer (NucA) with paclitaxel (PTX) through a linker to form a nucleolin aptamer–paclitaxel conjugate (NucA-PTX). NucA directs PTX to ovarian tumor cells for action with little effect on normal cells. Once NucA-PTX enters the tumor cells through endocytosis, the lysosomal protease in the cell will cleave the linker in NucA-PTX, thereby achieving the controlled release of PTX.

Fig. 15 Schematic of the MitoDNAts delivery system. Reproduced with permission from ref. 118. Copyright 2019, American Chemical Society.

Interestingly, a high payload delivery system means a powerful lethality to tumor cells.¹²⁰ As a typical example, Deng *et al.* proposed a general strategy to construct Aptamer–PolyproDrug Conjugates (ApPDCs); this method involved the assembly of aptamers targeting cancer cells, prodrugs and a biocompatible brush skeleton.¹²¹ Compared to traditional drug loading systems, ApPDCs have a high drug-to-aptamer ratio (DAPR ≥ 40). After the ApPDCs enter the cell, the reducing environment within the cell can trigger the efficient release of the prodrugs. By using prodrugs with different mechanisms, multi-drug synergy treatment can be achieved, and problems such as multi-drug resistance may be resolved.

Different from the above work, based on molecular engineering technology, the ratio of drugs can be adjusted accurately and multiple drugs can be precisely delivered to tumor cells. In this regard, Zhou *et al.* coupled circular bivalent aptamers with different drugs to prepare circular bivalent aptamer–drug conjugates (cb-ApDCs) with different drug dosing ratios.¹²² Drug release of cb-ApDCs can be monitored by confocal laser scanning microscopy; the ester bonds in cb-ApDCs can be cleaved by the esterase present in the late endosomes and lysosomes to realize the controlled release of drugs (Fig. 16b).

Fig. 16 (a) Preparation of cb-ApDCs. (b) Intracellular CPT release was monitored from intracellular cb-ApDCs. Reproduced with permission from ref. 122. Copyright 2019, Wiley-VCH.

3.3 Gene therapy

Chemically modified nucleic acid biopolymers can be combined with gene therapy technology to achieve highly efficient tumor treatment.¹²³

Gene therapy has the ability to combat many gene-related diseases and it is a promising cancer treatment strategy.¹²⁴ Li *et al.* designed a stimulus-responsive hydrogel for gene therapy, which was cross-linked by a building unit, a blocking and targeting unit and a linking unit (Fig. 17).¹²⁵ Different functional elements were integrated into the three building units, such as therapeutic genes that can induce apoptosis, DNA ribozymes that can inhibit cell migration, and aptamers that can target cancer cells. Glutathione in cells can effectively cleave the disulfide bonds in the building blocks to achieve dissociation of nano-hydrogels and release of multiple therapeutic genes. Moreover, Chen *et al.* synthesized molecular beacon micelle flares (MBMFs), which were assembled by diacyl lipids with circular DNA probes.¹²⁶ The premise of using MBMFs for gene therapy is to hybridize with mRNA first, and there are two main therapeutic mechanisms: one is to prevent translation from target mRNAs by providing translational blocking, and the other is to form a DNA/RNA

Fig. 17 Schematic of the hydrogel formation and gene therapy. Reproduced with permission from ref. 125. Copyright 2015, American Chemical Society.

Fig. 18 Schematic of gene therapy based on a DNA origami structure. Reproduced with permission from ref. 127. Copyright 2018, American Chemical Society.

hybrid with the target mRNA, which is subsequently degraded by the RNase H enzyme. Using these two mechanisms can inhibit the growth of cancer cells and realize gene therapy. Liu *et al.* used gene therapy to enhance antitumor effects.¹²⁷ Specifically, the authors constructed triangular DNA origami to load Dox, and then hybridized with the tumor therapeutic gene p53 to form a nano-kite assembly (Fig. 18). The assembly can effectively deliver p53 and DOX to tumor areas simultaneously, significantly enhancing the anti-tumor effect.

4. Conclusion and outlook

The addition of chemical modifications can impart rich structures and functions to nucleic acid biopolymers, attracting widespread attention from researchers. In this review, we introduced different cross-linking forms of chemically modified nucleic acid biopolymer nanostructures. Furthermore, we also summarized the applications of chemically modified nucleic acid biopolymers in biomolecule detection, controlled drug release, and gene therapy. These studies show the importance of chemically modified nucleic acid biopolymers in biosensing.

Although great achievements have been made, the application of chemically modified nucleic acid biopolymers in biosensing is still emerging and needs further improvement. For example, the efficiency of chemical modifications of nucleic acids needs to be further improved. Secondly, there is still an urgent requirement to develop nucleic acid biopolymers modified with different functional groups to achieve multifunctional biosensing. Finally, there are few chemically modified nucleic acid biopolymers available for clinical biosensing, so developing practical and safe chemically modified nucleic acid biopolymers is another key point. With the interdisciplinary development, chemically modified nucleic acid biopolymers have the potential to achieve greater promotions and breakthroughs in biosensing.
