Mixed valency in ligand-bridged diruthenium frameworks: divergences and perspectives

Arijit Singha Hazari,^a Arindam Indra^{*b} and Goutam Kumar Lahiri ^{*a}

The present review article illustrates the mixed valence aspects of ligand-bridged symmetric and unsymmetric diruthenium complexes beyond the textbook example of the Creutz–Taube ion as well as the Robin and Day classification by citing representative examples based on our recent observations. The consideration of varied coordination situations involving bridging and ancillary ligands of diverse electronic and steric demands extended important fundamental events including (i) the influence of ancillary ligands besides the bridge in the intermetallic coupling process, (ii) varying profile of the intervalence charge transfer (IVCT) transition in Ru^{III}Ru^{II} (d⁵d⁶) and Ru^{III}Ru^{IV} (d⁵d⁴) mixed valence set up, (iii) divergence between the electrochemical (K_c = comproportionation constant) and electronic (IVCT) coupling and (iv) occurrence of the hybrid class II–class III situation. Furthermore, additional challenges due to the introduction of redox non-innocent ligands in assigning valence and spin distributions at the metal–ligand interface as well as in differentiating the emerging alternatives of the radical-derived state and the mixed valence situation along the redox chain have been addressed.

1. Introduction

1.1. Mixed valence

Mixed-valence compounds are those that feature an element in more than one formal oxidation state. A sub-set of mixed valence compounds includes those in which two (or more) metal centers are linked through a bridging ligand. In particular

cases, the bridge can mediate intermetallic electron transfer from the reduced metal ion to the oxidized one.¹ The electron transfer at the mixed valence state is guided by various intriguing factors such as molecular conformation, separation of the redox centers, nature of the spacer and their redox potentials.²

In biological systems, the occurrence of polynuclear structures with metal ions in different oxidation states can be found in the oxygen evolving center (OEC) of photosystem II (PSII),³ cytochrome-*c*-oxidase,⁴ ferredoxins,⁵ etc. In PS II, four electrons and four protons are transferred through multistep processes involving high-energy intermediates. The proton-coupled

Arijit Singha Hazari received his B.Sc. degree from University of Calcutta and M.Sc. degree from Birla Institute of Technology and Science. He then joined IIT Bombay in 2013 to pursue his Ph.D. degree under the supervision of Prof. G. K. Lahiri. His research work primarily focusses on the electronic structural aspects of transition metal complexes involving redox-active ligands and their applications in homogeneous catalysis.

Dr. Arindam Indra received his Ph.D. from IIT Bombay (India) in solid supported catalysis. After completing his post-doctoral research from Technische Universität Berlin (Germany) and Hanyang University (Korea), he joined IIT (BHU), Varanasi (India) as an assistant professor. His group designs metal organic framework (MOF)-derived functional materials for energy conversion and storage.

Fig. 1 Oxygen evolving center (OEC) in photosystem II represents oxide-bridged mixed valent Mn^{III} and Mn^{IV} ions. Reprinted from ref. 6 with the permission of Wiley VCH.

Fig. 2 Alternate electronic forms of the Creutz–Taube ion.

electron transfer to produce molecular oxygen from water is eased by the mixed valent Mn^{III}–Mn^{IV} cluster in OEC (Fig. 1).⁶ Similarly, dioxygen activation is attained by mixed valent Cu^I/Cu^{II} centers in cytochrome-*c*-oxidase.⁷

Naturally occurring metal oxides (Spinel (A^{II}B^{III}₂O₄)) such as Fe₃O₄ (magnetite),⁸ Co₃O₄, Mn₃O₄ (ref. 9) and cyanide-bridged Prussian blue (Fe^{III}₄[Fe^{II}(CN)₆]₃·14H₂O, coordination polymer) or its analogues (PBA) also contain metal ions in different oxidation states.¹⁰

The mixed valency in the designed molecular framework was first described by Creutz and Taube¹¹ in the pyrazine-bridged diruthenium complex [(NH₃)₅Ru(μ-pyrazine)Ru(NH₃)₅]⁵⁺ (Fig. 2).

Similarly, Cowan's group¹² described the mixed valency in ferrocene (A) and ferrocenylene (B). Later, they introduced the tetrathiafulvalene radical cation (C in Fig. 3) as an odd-electron organic compound to show the mixed valency in an organic set up.¹³

Prof. Goutam Kumar Lahiri received his Ph.D degree from Jadavpur University (IACS) in 1990 under the supervision of Prof. Animesh Chakravorty. After completing his postdoctoral studies at West Virginia University, USA, he joined the department of chemistry at IIT Bombay in 1993, where he is currently an Institute Chair Professor. The main theme of his research is centered around the electron

transfer aspects and catalytic features of transition metal complexes.

Fig. 3 Electron transfer series of tetrathiafulvalene.

Under the purview of the broader context of mixed valency, diruthenium complexes have been extensively investigated to understand the bridge-mediated electron transfer in mixed valent Ru^{II}(d⁶)Ru^{III}(d⁵) systems primarily due to better kinetic stability of varying (+2, +3 or even +4) oxidation states of the ruthenium ion.¹⁴

Mixed valence complexes were initially synthesized to understand the fundamental aspects of intermetallic electronic coupling processes.¹⁵ Later, the focus was also directed towards exploring potential applications of the mixed valence compounds in molecular electronics, molecular wires and quantum automata.¹⁶ In nanochemistry, the intramolecular electron transfer can be employed to demonstrate the nano-junction device of bulk metal–single molecule–bulk metal.¹⁷ A mixed valence compound that derived molecular switch for long-range electron transfer (15–20 Å) was also investigated.¹⁸

1.2. Classification of mixed valence complexes

In a ligand-bridged diruthenium(II/III) complex [(AL)Ru^{II}(μ-BL)Ru^{III}(AL)] (BL = Bridging ligand and AL = ancillary or peripheral ligand), the electron transfer is initiated from the starting metal center to the arrival site through a bridging ligand (BL). Thus, the bridging ligand plays the role of a mediator to exchange the odd electron between the metal centers at the termini. Hence, the electronic nature and the composition of the bridge play important roles in governing the rate of electron transfer. This provides useful information regarding the separation of the redox potential between the metal centers under chemically identical environments (symmetric set up). In this context, superexchange mechanism provides a better perception about the bridge-mediated intermetallic interaction, which involves efficient overlap of the metal d-orbitals and the π-orbitals of the spacer (through bond interaction). It can be conceived as a sequential electron transfer between the molecular orbitals of the ligand (π type) and the metal (dπ type), resulting in delocalization of the electron density across the

Fig. 4 Bridging ligand-mediated electron transfer and hole transfer pathways in mixed valence complexes.^{19c,d}

metal–bridge–metal domain to some extent, and it occurs *via* either of the following two pathways (Fig. 4):¹⁹

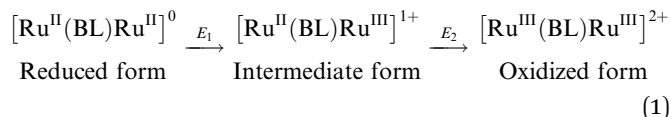

Electron transfer pathway. This is operative when the bridging ligand contains low-lying empty π^* -orbitals (LUMO), *i.e.*, π -acceptor in nature.

Hole transfer pathway. This is followed when the bridging ligand contains high-lying filled π -orbitals (HOMO), *i.e.*, electron rich in nature.

Robin and Day classified²⁰ the mixed valence complexes based on the extent of intermetallic interaction. A very weak to negligible interaction between the metal centers is defined as a class I system, whereas a moderate coupling results in a localized valence-trapped class II ($[(\text{AL})\text{Ru}^{\text{II}}(\mu\text{-BL})\text{Ru}^{\text{III}}(\text{AL})]$) system. On the other hand, strong intermetallic coupling leads to a valence delocalized $[(\text{AL})\text{Ru}^{2.5}(\mu\text{-BL})\text{Ru}^{2.5}(\text{AL})]$ class III set up. Therefore, detailed studies with varied molecular frameworks have been conducted over the past decades to understand the role of metal ions and ligands (ancillary and bridging) in modulating the intermetallic electronic coupling at the mixed valence state.²¹

1.3. Comproportionation constant

Comproportionation constant, K_c , implies the thermodynamic stability of the intermediate redox state. For a two-step redox reaction (eqn (1)), the comproportionation constant (K_c) can be calculated from the potential difference (ΔE) of the successive redox couples.²²

$$K_c = \frac{[\text{intermediate form}]^2}{[\text{reduced form}][\text{oxidized form}]}$$

at 298 K,

$$\Delta G_c = -RT(\ln K_c) = -nF(\Delta E^0); (\Delta E = E_2 - E_1)$$

$K_c = 10^{\Delta E/0.059V}$, ΔE is the separation between the redox potentials of the successive redox processes.

For a well-defined metal-based redox process, K_c signifies the thermodynamic stability of the mixed valence state. For example, successive $\text{Ru}^{\text{II}}/\text{Ru}^{\text{III}}$ redox couples in the Creutz-Taube ion are well separated by 0.39 V ($K_c = 10^{6.6}$), leading to a stable mixed valence state with respect to the disproportionation reaction that produces isoivalent $\text{Ru}^{\text{II}}/\text{Ru}^{\text{II}}$ and $\text{Ru}^{\text{III}}/\text{Ru}^{\text{III}}$.^{11a,23}

According to the Robin and Day classification, a genuine non-interacting class I system is defined by a statistical K_c value of 4, whereas K_c values close to 10^5 and greater than 10^6 correspond to class II and class III systems, respectively.²³ In a qualitative sense, K_c values ranging in between the valence localized class II and the valence delocalized class III may represent a borderline class II/III hybrid situation. Despite the Robin and Day classification of the intermetallic interaction based on the value of K_c , the equilibrium constant alone cannot provide an evaluation of the metal–metal electronic coupling since the free energy of the comproportionation reaction (ΔG_c) consists of several interplaying factors (eqn (2)).²⁴

$$\Delta G_c = \Delta G_s + \Delta G_e + \Delta G_i + \Delta G_r + \Delta G_{af} + \Delta G_{ip} \quad (2)$$

In eqn (2), ΔG_s corresponds to the statistical distribution, ΔG_e reflects the electrostatic repulsion between the positively charged metal ions, ΔG_i accounts for the inductive factor related to the competitive coordination of the bridging ligand by the metal ions, ΔG_r is the free energy of the resonance exchange, ΔG_{af} relates to the antiferromagnetic exchange stabilization of the isoivalent higher analogue state $\text{M}^{n+1}\text{M}^{n+1}$ over that of its mixed valent form M^nM^{n+1} and ΔG_{ip} represents the ion-pairing effect, which changes its magnitude depending on the charge of the complex moiety. However, in the case of hole transfer mechanism, the value of ΔG_{af} becomes almost insignificant. Although K_c extends the *prima facie* information regarding the extent of the intermetallic interaction in a three-state arrangement, precautionary measures need to be taken into account. This is primarily due to the dependence of redox potentials on the nature of the solvent (dielectric constant or nucleophilicity) as well as counter ions (ion-pairing ability), which can affect the value of ΔG_c appreciably.^{24b} Thus, to extract the extent of electronic coupling leading to valence localization or delocalization at the mixed valence state, the collective consideration of K_c and the intervalence charge transfer (IVCT) feature are rather necessary.

1.4. Intervalence charge transfer (IVCT) transition

In the case of a weakly coupled valence localized system, the charge transfer occurs from the metal in a lower oxidation state (electron rich) to the metal in a higher oxidation state (electron deficient), resulting in bridge-mediated uni-directional intervalence charge transfer transition (IVCT band) at the low-energy NIR region of electron absorption spectroscopy.²⁵ The correlation of IVCT band with electronic coupling between the metal

centers at the mixed valence state follows the Hush formula.²⁶ For class II type complexes, the bandwidth at half-height ($\Delta\nu_{1/2}$) of IVCT is related to the energy maximum (eqn (3)):

$$\Delta\nu_{1/2} = [2.31 \times 10^3 (E_{\max})]^{1/2} \quad (3)$$

In the case of a symmetrical band, IVCT can be correlated with the electronic coupling constant (V_{ab}) by eqn (4),

$$V_{\text{ab}} = \{[2.05 \times 10^{-2} (\epsilon_{\max} \bar{\nu}_{\max} \bar{\nu}_{1/2})^{1/2}] / R\} \quad (4)$$

where ϵ_{\max} is the molar extinction coefficient, $\bar{\nu}_{\max}$ is the absorption maximum in wavenumbers, $\bar{\nu}_{1/2}$ is the bandwidth at half-height in wavenumbers and R is the metal–metal distance in Å. However, the effective metal–metal distance can also vary significantly depending on the extent of the mixing of orbitals of the bridge and the metal ions at the termini.²⁷

For a fully delocalized class III system, the calculated $\Delta\nu_{1/2}$ value of the IVCT band using the Hush equation is always higher than the experimentally obtained value, and V_{ab} amounts to $\bar{\nu}_{\max}/2$.

Please note that the valence localized class II system exhibits a double well potential. On the contrary, the extensive charge delocalization between the donor and acceptor sites in the class III system results in the disappearance of separate minima, exhibiting single minimum in the energy surface instead.

The larger bandwidth at half-height ($\Delta\nu_{1/2}$) of IVCT for the weakly coupled (class II) system than that for the strongly coupled (class III) system can be due to the transition from the flat potential energy (PE) surface to a steep one in the former and the transition from the flat PE surface to another flat PE surface in the latter.^{15b}

In fact, the correlation between the IVCT band and the intermetallic coupling is not so straightforward as the band shape, bandwidth and intensity vary appreciably depending on the solvent polarity and electronic and vibrational motions.^{28,29} In the case of class III-type mixed valency, the motions from the solvent and vibrations are averaged to delocalize the electron density. This results in narrow solvent-independent IVCT bands. In class II-type, the IVCT band is broad and depends on the dielectric constant of the solvent as the motions from the exchange of electrons and the solvent are localized. On the contrary, in the borderline (hybrid) class II–III system, the solvent dynamic parameters play influential roles in controlling the rate of the intermolecular electron transfer by minimizing the impact of the solvent reorganization energy or polarity.^{23b} Additionally, the parameter “ T ” ($T = 1 - (\Delta\nu_{1/2}) / (16 \ln(2)RT)^{1/2}$) introduced by Sutin and co-workers has been widely acknowledged in identifying the intriguing situation of the class II–III hybrid system.^{15b} The room-temperature limiting value of T can distinguish between the weakly coupled class I ($0 < T < 0.1$), moderately coupled class II ($0.1 < T < 0.5$), class II–III hybrid ($T \approx 0.5$) and class III ($T > 0.5$) systems.

1.5. Vibrational and electron spin resonance spectroscopy

In this context, vibrational (IR and Raman) spectroscopic techniques have been considered to be very effective for the

selectively designed molecular frameworks containing suitable functional groups such as CO, NO, and CN to extract more precise information relating to the valence localization or delocalization process at the mixed valence state with a faster picosecond to femtosecond time scale.³⁰

The correlation of EPR g parameters (g -anisotropy, $\Delta g = g_1 - g_3$ and $\langle g \rangle = \{1/3(g_1^2 + g_2^2 + g_3^2)\}^{1/2}$,³¹ hyperfine splitting) with the DFT calculated spin density distribution at the metal–bridge–metal domain of the paramagnetic mixed valence state provides additional justification in favor of the valence localization or delocalization process.³² However, a mixed valence state without any EPR response is not so uncommon, particularly due to the rapid relaxation process. This situation may improve upon moving to the liquid helium temperature (4 K).³³

It should be noted that the time scale of a particular spectroscopic technique also plays a critical role in establishing the mixed valence feature. It may give rise to contradictory observations based on the rate of the electron transfer, solvent reorganization process and solvent dynamics. The slower time scale of the EPR spectroscopic technique (10^{-5} to 10^{-9} s) often fails to distinguish the valence localized and delocalized situations, whereas a faster vibrational spectroscopy technique ($\sim 10^{-12}$ s) is found to be more precise in this regard.³⁴

1.6. Diruthenium complexes involving a redox active bridge

In a specialized situation relating to the selective participation of bridge-based Frontier orbitals in the redox processes of the complex moieties, an additional complexity arises due to the probable alternate formation of a radical bridged isovalent state ($[(\text{AL})\text{Ru}^{\text{II}}(\mu\text{-BL})\text{Ru}^{\text{II}}(\text{AL})] - e^- \rightarrow [(\text{AL})\text{Ru}^{\text{II}}(\mu\text{-BL}^{\cdot})\text{Ru}^{\text{II}}(\text{AL})]^+$) upon electron transfer instead of the otherwise expected mixed valence state ($[(\text{AL})\text{Ru}^{\text{II}}(\mu\text{-BL})\text{Ru}^{\text{III}}(\text{AL})]$).³⁵ Therefore, appropriate care needs to be taken in formulating the electronic structure of the redox states as well. In this context, EPR g -anisotropy in conjunction with DFT-calculated spin distribution at the paramagnetic intermediate state can facilitate to differentiate the alternative mixed valence state *versus* the radical-bridged isovalent state.

The present review article highlights our recent observations concerning the divergent issues in addressing mixed valency in ligand-bridged diruthenium systems by citing the following representative cases.

2. Metal-centered mixed valency

2.1. Role of the ancillary ligand

Pyrazine-mediated facile intramolecular electron transfer in the mixed valent Creutz–Taube ion essentially leads to the development of analogous bis-tridentate non-planar 2,3,5,6-tetrakis(2-pyridyl) pyrazine (tppz)-bridged isovalent diruthenium(II) complexes ($[(\text{AL})(\text{Cl})\text{Ru}^{\text{II}}(\mu\text{-tppz})\text{Ru}^{\text{II}}(\text{Cl})(\text{AL})]^n, 1^n$).³⁶ The impact of a set of ancillary ligands (AL) with varying electronic demands in the mixed valent $\text{Ru}^{\text{II}}\text{Ru}^{\text{III}}$ state (1^n) was explored (Table 1) *via* an experimental investigation in

conjunction with DFT calculations. Successive two-step reversible electrochemical oxidations of isovalent $\text{Ru}^{\text{II}}\text{Ru}^{\text{II}}$ (1^n) complexes resulted in a mixed valent $\{\text{Ru}^{\text{II}}(\mu\text{-tppz})\text{Ru}^{\text{III}}\}$ intermediate ($1^{(n+1)}$) followed by the isovalent higher $\{\text{Ru}^{\text{III}}(\mu\text{-tppz})\text{Ru}^{\text{III}}\}^{\text{I}}$ congener ($1^{(n+2)}$). The detailed structural, electrochemical, spectroscopic and theoretical investigations revealed that in addition to the bridge, the electronic nature (σ -donating to π -acidic to strongly π -acidic) of the ancillary ligand (AL) also played an important role in tuning the mixed valence feature (K_c as well as IVCT, Table 1). The enhanced electron density on the metal ions *via* the insertion of an electron-rich ancillary ligand facilitated the intramolecular electron transfer process with larger K_c and intense IVCT (borderline class II–III to class III), whereas a reverse pattern (smaller K_c and weak IVCT) was apparent for the acceptor-type ancillary ligand. Please note that to the best of our knowledge, a well-defined valence-localized (weakly coupled) class II mixed valence system involving a tppz-bridged diruthenium system is not reported so far.

Table 1 Varying K_c and IVCT as a function of the ancillary ligand

^a The classification (class III or class II–III) was defined primarily based on the K_c and IVCT band features by following the Hush formula as stated in Sections 1.3 and 1.4.

2.2. $\text{Ru}^{\text{II}}\text{Ru}^{\text{III}}$ (d^6d^5) versus $\text{Ru}^{\text{III}}\text{Ru}^{\text{IV}}$ (d^5d^4) mixed valence systems

Though numerous examples of ligand-bridged $\text{Ru}^{\text{II}}\text{Ru}^{\text{III}}$ mixed valence systems are available in the literature,³⁷ only a few well-defined $\text{Ru}^{\text{III}}\text{Ru}^{\text{IV}}$ mixed valence systems (D and E) are reported so far.^{38b,c}

In this context, bis-chelating dianionic oxamidato-bridged diruthenium(III) complex 2^n ($n = 0$) in $S = 1$ ground state ($J = -40 \text{ cm}^{-1}$) exhibited two successive oxidative ($\text{Ru}^{\text{III}}\text{Ru}^{\text{III}}$ (2) \rightarrow $\text{Ru}^{\text{III}}\text{Ru}^{\text{IV}}$ (2^+) \rightarrow $\text{Ru}^{\text{IV}}\text{Ru}^{\text{IV}}$ (2^{2+}), O1/O2) and reductive ($\text{Ru}^{\text{III}}\text{Ru}^{\text{III}}$ (2) \rightarrow $\text{Ru}^{\text{III}}\text{Ru}^{\text{II}}$ (2^-) \rightarrow $\text{Ru}^{\text{II}}\text{Ru}^{\text{II}}$ (2^{2-}), R1/R2) couples with moderate K_c values of $10^{5.8}$ and $10^{5.9}$ for mixed valent $\text{Ru}^{\text{III}}\text{Ru}^{\text{IV}}$ and $\text{Ru}^{\text{III}}\text{Ru}^{\text{II}}$, respectively (Fig. 5).

Both the electrochemically generated mixed valence states $\text{Ru}^{\text{III}}\text{Ru}^{\text{II}}$ (2^-) and $\text{Ru}^{\text{III}}\text{Ru}^{\text{IV}}$ (2^+) displayed moderately intense broad IVCT bands in the NIR region at 1800 nm ($\epsilon/\text{M}^{-1} \text{cm}^{-1}$: 2100) and 1500 nm ($\epsilon/\text{M}^{-1} \text{cm}^{-1}$: 2200), respectively, corresponding to the class II system. The appearance of a relatively broader IVCT band for the $\text{Ru}^{\text{III}}\text{Ru}^{\text{IV}}$ (d^5d^4) mixed valence state

Fig. 5 Cyclic (black) and differential pulse (red) voltammograms of **2** in CH_3CN (top). UV-vis-NIR spectroelectrochemistry in CH_3CN and the sketch for IVCT and IC transitions (bottom).

compared to that for the $\text{Ru}^{\text{III}}\text{Ru}^{\text{II}}$ (d^5d^6) mixed valence state could possibly be due to more number of intervalence (IVCT) and d-d (IC) transitions in the former with respect to that in the latter because of the presence of three and one holes at metal t_{2g} levels, respectively (Fig. 5). Thus, 2^n represents a novel example demonstrating two mixed valence intermediates $\text{Ru}^{\text{III}}\text{Ru}^{\text{II}}$ (via reductive pathway) and less common $\text{Ru}^{\text{III}}\text{Ru}^{\text{IV}}$ (via oxidative pathway).³⁸

2.3. Paradox between K_c and IVCT

According to the Robin and Day classification and Hush formalism, a symmetric class III molecular set is expected to display large K_c and an intense IVCT band in the NIR region.^{26,39} However, the mixed valent ($\text{Ru}^{\text{II}}\text{Ru}^{\text{III}}$) complex **3**⁺ failed to display the expected low-energy IVCT band up to 2500 nm despite the very large K_c value of $10^{13.9}$.⁴⁰ On the other hand, the previously reported analogous complex **4**⁺ exhibited a solvent-independent and very weak IVCT band ($\epsilon/\text{M}^{-1}\text{cm}^{-1}$: 20) with a similar K_c value of $10^{13.6}$.⁴¹ The absence of the IVCT band despite the very large K_c value in **3**⁺ appeared to be rather puzzling. Though we were unable to offer any simple explanation, very weak to undetectable IVCT bands were also observed earlier for mixed valent ruthenium complexes with appreciably large K_c values.⁴²

On the other hand, 2,5-pyrazine-dicarboxylate (BL)-bridged iso-valent diruthenium(III) complex (**5**ⁿ ($n = 0$)) (acac = acetylacetonate) in $S = 1$ ground state ($J = -1.78\text{ cm}^{-1}$) displayed successive $\text{Ru}^{\text{III}}/\text{Ru}^{\text{II}}$ redox couples with K_c of 10^7 .⁴³ Stepwise one-electron reductions facilitated the generation of a mixed-valent intermediate $[(\text{acac})_2\text{Ru}^{\text{III}}(\mu\text{-BL})\text{Ru}^{\text{II}}(\text{acac})_2]^-$ (**5**⁻) followed by iso-valent $[(\text{acac})_2\text{Ru}^{\text{II}}(\mu\text{-BL})\text{Ru}^{\text{II}}(\text{acac})_2]^{2-}$ (**5**²⁻) in lower oxidation states. The mixed valent **5**⁻ exhibited an Ru^{III} -based anisotropic EPR spectrum ($\Delta g = 0.32$). However, the very weak IVCT band of the intermediate **5**⁻ at 1040 nm ($\epsilon = 380\text{ M}^{-1}\text{cm}^{-1}$) implied limited electronic communication between the two metal centers ($\{\text{Ru}^{\text{III}}(\mu\text{-BL})\text{Ru}^{\text{II}}\}$, class II) despite the appreciably high K_c value of 10^7 . The diverse inference regarding the mixed valence feature of **5**⁻ based on K_c (class III) and IVCT (class II) was however addressed via IR spectroelectrochemistry (Fig. 6). The unsplit $\nu(\text{C}=\text{O})$ bands of the carboxylate groups of BL for mixed valent **5**⁻ as those for iso-valent **5** or **5**²⁻ indeed suggested a delocalized ($\text{Ru}^{2.5}\text{Ru}^{2.5}$, class III to borderline class II-III) situation even at the vibrational time scale.

Fig. 6 Shift in the $\nu(\text{C}=\text{O})$ frequency on moving from **5** \rightarrow **5**⁻ and **5**⁻ \rightarrow **5**²⁻ in CH_3CN .

On the contrary, 6^{3+} and 7^{3+} exhibited intense IVCT bands despite small K_c values.⁴⁴

Fig. 7 Cyclic voltammograms of 8^{2+} in CH_3CN .

2.4. Unsymmetrical diruthenium complexes

Asymmetry in dinuclear frameworks can be introduced by using different ancillary ligands at the metal sites or by using an unsymmetrical bridge or even by coordination to two different metal ions.⁴⁵ Unlike that in a symmetrical system, the donor center asymmetry (ancillary or bridging ligand) around the metal ions in an unsymmetrical system makes it rather challenging to quantify the contribution of intermetallic electrochemical coupling (K_c) out of the potential separation of the successive redox processes.

In this context, unsymmetrical diruthenium(II) complexes $8a^{2+}$, $8b^{2+}$ and $8c^{2+}$ exhibited two successive oxidation processes ($Ru^{II}Ru^{II}/Ru^{II}Ru^{III}$ and $Ru^{II}Ru^{III}/Ru^{III}Ru^{III}$) via the intermediate mixed valent $Ru^{II}Ru^{III}$ state (Fig. 7).⁴⁶ The separation in potential between the stepwise redox processes led to the K_c values of 10^4 , 10^2 and 10^{14} for the intermediates $8a^{3+}$, $8b^{3+}$ and $8c^{3+}$, respectively. The 100-fold larger K_c value of $8a^{3+}$ with respect to that of $8b^{3+}$ was due to moderate and strong π -acceptor features of bpy and pap, respectively. On the other hand, the very large K_c value of 10^{14} for $8c^{3+}$, which comprised metal fragments with two distinctly different acceptor ligands bpy (moderate π acceptor) and pap (strong π acceptor) could be the reflection of three simultaneously operating effects: (i) effect of unsymmetrical ancillary ligand, (ii) effect of unsymmetrical bridging ligand and (iii) bridging ligand-mediated electrochemical coupling between the reduced and oxidized metal ions. The very weak IVCT band at the near IR region corresponding to $8a^{3+}$ and $8b^{3+}$ in conjunction with low K_c values of 10^4 and 10^2 , respectively, suggested the class II mixed valence state. However, the unstable nature of the electrochemically generated $6c^{3+}$ restricted us from assigning its mixed valence feature.

Similarly, a cyano-bridged unsymmetric mixed valence^{45g} dinuclear complex $[(NH_3)_5-Ru-(\mu-CN)Fe(CN)_5]^-$ involving

different metal ions and ancillary ligands was assigned to be a valence-localized class-II system (eqn (5)) primarily based on its optical (IVCT) features and electrochemical aspects as a function of the solvent polarity and the charges of cations and anions of the electrolytes.^{45f}

3. Involvement of redox non-innocent ligands

The closeness of the Frontier orbitals of ruthenium and redox active (non-innocent) ligands leads to the feasibility of alternate electronic structural forms including resonating configuration⁴⁷ instead of any precise valence description along the redox chain.⁴⁸ In certain instances, the redox-induced electron-transfer process (RIET) is also considered to be operational.⁴⁹ Appropriate care is therefore needed in assigning the valence distribution process at the metal-ligand interface of such molecular forms.

A few representative cases involving multi-redox sites (metal, bridge or ancillary ligands) within the discrete molecular set up are therefore highlighted below.

3.1. Active bridge and ancillary ligand

Experimental and theoretical investigations of two successive reversible oxidation processes (O1/O2) of the deprotonated ellagate-bridged diruthenium(II) complex 9^n ($n = 0$) (Fig. 8) revealed selective participation of bridge-based orbitals in the

Fig. 8 Cyclic voltammograms of 9 in CH₃CN.Fig. 9 Electronic structural forms along the redox chain including the Mulliken spin density plot for 9⁺.

redox processes ($9 \rightarrow 9^+$ (O1) and $9^+ \rightarrow 9^{2+}$ (O2) in Fig. 8), *i.e.*, a catecholate/semiquinone-based redox system instead of otherwise expected metal-based (Ru^{II}/Ru^{III}) oxidations.⁵⁰ The intermediate radical-bridged isovalent metal (Ru^{II}) centers in 9^+ exhibited free radical EPR ($g_1 = 2.011$, $g_2 = 2.002$, $g_3 = 1.987$; $\Delta g = 0.024$, $\langle g \rangle = 2.000$), which was corroborated by the calculated bridge-dominated spin (96%) and the intense LLCT (donor radical bridge to π -accepting pap) transitions in the NIR region around 2000 nm ($\epsilon/M^{-1} \text{ cm}^{-1}$: 1843) (Fig. 8). Successive reductions (R1 (9^{2-}), R2 (9^{4-}), two-electron each) of the fully reduced bridge-based 9 were however associated with the azo ($-N=N-$, $pap^0/pap^{\cdot-}/pap^{2-}$, as shown above) function of pap (Fig. 9).

3.2. Active ancillary ligand

Structural, spectroscopic and magnetic studies showed that the uncoupled semiquinone ancillary ligands stabilized the tppz-bridged diruthenium(II) complex 10^n ($n = 0$) in the triplet ($S = 1$, $J = -3.07 \text{ cm}^{-1}$) ground state.⁵¹ Stepwise oxidations (O1, O2) and reductions (R1, R2) of complex 10 yielded the calculated K_c values of 10^2 and 10^4 , respectively, for the intermediate states (Fig. 10). The pertinent question regarding the involvement of ancillary ligand (quinone (Q), semiquinone ($Q^{\cdot-}$) and catecholate (Q^{2-})), bridge (tppz⁰, tppz^{\cdot-}, tppz²⁻) and metal (Ru^{II} , Ru^{III} , Ru^{IV})

Fig. 10 Cyclic voltammogram of 10 in CH₃CN.Fig. 11 Electronic structural forms of 10^n in accessible redox states. Boldface refers to the dominating forms.

in accessible redox processes of 10^n was ascertained *via* the collective consideration of experimental and theoretical investigations. It revealed the preferential participation of ancillary ligands in both oxidation ($Q^{\cdot-}$ to Q^0) and reduction ($(Q^{\cdot-}$ to $Q^{2-})$) processes, leaving the metal ion as the silent spectator (Fig. 11).

Fig. 12 Cyclic (black) and differential pulse (red) voltammograms in CH_3CN .

Fig. 13 Electronic structural forms of 11^n and 12^n .

3.3. Active bridge, ancillary ligand and metal

Dianionic DPAPP^{2-} ($\text{H}_2\text{DPAPP} = 2,5$ -dihydro-3,6-di-2-pyrrolylpyrrolo[3,4-*c*]pyrrole-1,4-dione)-bridged diruthenium(II) complexes 11^{2+} and 12^{2+} displayed two successive oxidations and multiple reductions within the potential window of ± 2.0 V *versus* SCE (Fig. 12).⁵² DFT and TD-DFT-supported experimental studies established bridge-based first oxidation ($\text{DPAPP}^{2-} \rightarrow \text{DPAPP}^{\cdot-}$ (O1, Fig. 12)), followed by metal oxidation (O2, Fig. 12), whereas the first two reversible reductions were associated with DPAPP^{2-} ($\text{DPAPP}^{2-} \rightarrow \text{DPAPP}^{3-}$) or the ancillary ligand based on the relative π -accepting strength of the latter (*bpy* *versus* *pap*) (Fig. 13).

The occurrence of the radical-bridged isoivalent situation along the redox chain was also evident by free radical EPR ($g_{\text{iso}} = \sim 2.005$) and the moderately intense inter-ligand (LLCT) low-energy band in the NIR region (2036 nm, ($\epsilon/\text{M}^{-1} \text{cm}^{-1}$): 2410).

3.4. Unusual spin interaction

Twisted doubly reduced BL^{2-} ($\text{BL}^{2-} = 1,4$ -dioxido-2,3-bis(3,5-dimethylpyrazol-1'-yl)benzene)-bridged $[(\text{acac})_2\text{Ru}^{\text{III}}(\mu\text{-BL})\text{Ru}^{\text{III}}(\text{acac})_2]^n$ (13^n ($n = 0$)) ($\text{acac} = \text{acetylacetonate}$) in $S = 1$ state ($J = -37 \text{ cm}^{-1}$) exhibited two successive oxidations (O1, O2) and reductions (R1, R2) (Fig. 14).⁵³

UV-vis-NIR spectroelectrochemistry (Fig. 15) and EPR (Fig. 16) collectively corroborated metal-based reductions, $\text{Ru}^{\text{III}}\text{Ru}^{\text{III}}$ (13) \rightarrow $\text{Ru}^{\text{III}}\text{Ru}^{\text{II}}$ ($13^{\cdot-}$, R1) \rightarrow $\text{Ru}^{\text{II}}\text{Ru}^{\text{II}}$ (13^{2-} , R2). The mixed valent $13^{\cdot-}$ displayed an anisotropic Ru^{III} -based EPR spectrum ($g_1 = 2.40$, $g_2 = 2.19$, $g_3 = 1.79$; $\Delta g = 0.061$, (g^{\cdot}) = 2.14) and a broad IVCT band at 1520 nm ($\epsilon/\text{M}^{-1} \text{cm}^{-1}$: 1000; $\Delta\nu_{1/2}$ (calculated/experimental): 3898/5000 cm^{-1}), corresponding to the valence localized class II system, as also suggested by K_c of $10^{3.7}$. However, the IVCT band of $13^{\cdot-}$ disappeared on further reduction to the isoivalent $\text{Ru}^{\text{II}}\text{Ru}^{\text{II}}$ state in 13^{2-} . A reversible first oxidation (O1, $13 \rightarrow 13^+$) resulted in an intense NIR band at 892 nm ($\epsilon/\text{M}^{-1} \text{cm}^{-1}$: 11 600) and a free radical EPR at $g =$

Fig. 14 Cyclic (black) and differential pulse (red) voltammograms of 13 in CH_3CN .

Fig. 15 UV-vis-NIR spectroelectrochemistry of 13^n in CH_3CN .

2.005. The observed free radical EPR of 13^+ could be rationalized by considering the electronic form of $[(\text{acac})_2\text{Ru}^{\text{III}}(\mu\text{-BL}^{\bullet-})\text{Ru}^{\text{III}}(\text{acac})_2]^+$ with an up-up-down ($\uparrow\uparrow\downarrow$) spin configuration, where the antiferromagnetic coupling between the remote metal spins left the unpaired spin on the bridge. The alternate three-spin arrangement with the up-down-up ($\uparrow\downarrow\uparrow$) spin configuration in the ground state would favor metal-centered spin through antiferromagnetic coupling between the spins associated with one of the ruthenium ions and the radical bridge.

4. Conclusion and perspectives

Although mixed valence aspects of transition metal complexes have been covered quite extensively in existing literature, the present deliberation indicates the further scope of expansion depending on the conspicuous nature of the bridge in a three-state mixed valence system.

The present review article essentially highlighted the emerging diverse fundamental aspects relating to the mixed valency in ligand-bridged symmetric and unsymmetric

diruthenium complexes by citing selective recent cases. It demonstrated the impact of the electronic nature of both ancillary and bridging ligands in tuning the intramolecular electron transfer process at the mixed valence state ($\text{Ru}^{\text{II}}\text{Ru}^{\text{III}}$ or $\text{Ru}^{\text{III}}\text{Ru}^{\text{IV}}$). It also addressed the pertinent additional issues regarding valence and spin situations due to the introduction of redox active ligands in complex frameworks. Moreover, the necessary cautions with special references to the comproportionation constant (K_c) and the possible low-energy (NIR) ligand-to-ligand charge transfer (LLCT) transition instead of the usual metal-based IVCT transition for redox-active ligand-derived systems were noted.

Besides the well explored application potential of mixed valence complexes for molecular wires,⁵⁴ molecular switches⁵⁵ or telecommunication devices,⁵⁶ the recent revelations of superior conductivity of transition metal-derived metal-organic frameworks (beyond the classical discrete metal complexes) due to better orbital overlapping at the mixed valent state⁵⁷ as well as involvement of mixed valent state in the water oxidation process⁵⁸ would provide additional impetus in developing more fundamentally challenging or attractive mixed valent systems.

Thus, further research activities with fundamentally rich and diversified mixed valence compounds would likely expand the scope of designing new generation molecular electronic devices and provide a better understanding of the electron transfer phenomenon in a complex molecular set up.
