Diamond surface engineering for molecular sensing with nitrogen–vacancy centers

Erika Janitz, Konstantin Herb, Laura A. Völker,  William S. Huxter, 
Christian L. Degen and John M. Abendroth *

Quantum sensing using optically addressable atomic-scale defects, such as the nitrogen-vacancy (NV) center in diamond, provides new opportunities for sensitive and highly localized characterization of chemical functionality. Notably, near-surface defects facilitate detection of the minute magnetic fields generated by nuclear or electron spins outside of the diamond crystal, such as those in chemisorbed and physisorbed molecules. However, the promise of NV centers is hindered by a severe degradation of critical sensor properties, namely charge stability and spin coherence, near surfaces (< ca. 10 nm deep). Moreover, applications in the chemical sciences require methods for covalent bonding of target molecules to diamond with robust control over density, orientation, and binding configuration. This forward-looking Review provides a survey of the rapidly converging fields of diamond surface science and NV-center physics, highlighting their combined potential for quantum sensing of molecules. We outline the diamond surface properties that are advantageous for NV-sensing applications, and discuss strategies to mitigate deleterious effects while simultaneously providing avenues for chemical attachment. Finally, we present an outlook on emerging applications in which the unprecedented sensitivity and spatial resolution of NV-based sensing could provide unique insight into chemically functionalized surfaces at the single-molecule level.

1 Introduction

Nuclear and electron spins within molecules provide invaluable handles with which to identify chemical structures and intermolecular interactions, allowing for visualization of physiological processes and biological matter for medical diagnostics. Moreover, observing the spin dynamics of transient reaction intermediates could provide new insights into spin-selective chemistries. Traditional methods for performing such characterizations include nuclear magnetic resonance (NMR) and electron paramagnetic resonance (EPR) spectroscopy.^{1–4} Unfortunately, these conventional techniques commonly rely on large spin ensembles to overcome low thermal polarization and suffer from poor detection efficiency, which preclude the study of dilute spin samples.^{5–7} In addition, spatial resolution is hampered by the challenge of applying large magnetic gradients with nanoscale precision.^{8,9} Therefore, the grand goal of studying individual molecules (spins) requires a fundamentally different experimental approach.

One such approach replaces traditional NMR and EPR detectors with single, individually addressable quantum spins, which are capable of detecting the minute magnetic fields generated by

nuclei or unpaired electrons in nearby molecules.^{10,11} In particular, the nitrogen–vacancy (NV) center in diamond has emerged as a promising candidate sensor for molecular analysis due to its exquisite magnetic-field sensitivity, nanoscale spatial resolution, biocompatibility, and operational capacity under ambient conditions.^{12–20} Already in the context of chemical sensing, the atomic scale of such defects has been exploited to probe nanoscale magnetic fluctuations with nanoscale resolution,^{21,22} facilitating the study of dilute protein assemblies,^{23,24} DNA,²⁵ and paramagnetic species²⁶ with single NVs, as well as detection of NMR chemical shifts in proximal molecules.^{27–29} However, the weak dipolar fields generated by target spins decay rapidly with target–sensor separation, motivating the use of near-surface NVs and direct molecular functionalization of the diamond surface. In such cases, the exquisite sensitivity of the NV center presents a challenge in the presence of surface noise, which degrades charge stability and spin coherence for shallow defects.^{30,31} Thus, improving near-surface NV properties while simultaneously enabling chemical functionalization of the diamond surface represents a critical multidisciplinary challenge.

This Review begins with a tutorial-style introduction to the NV center electronic structure and sensing properties, focusing on detection of magnetic fields since it is the most prevalent sensing modality. We include a brief complementary summary of electric-field, strain, and temperature sensing, which may

prove useful in future surface-chemistry characterization. We follow with a discussion of measurement sensitivity and other relevant figures of merit, elucidating which experimental

parameters are most important for chemical characterization with shallow defects. Next, we explore the origins of instabilities that plague near-surface NV centers along with experimental

Erika Janitz

Dr Erika Janitz earned a BSc in electrical engineering from the University of Waterloo (2012) and a MSc in electrical engineering with a specialization in quantum information from the Institute for Quantum Computing (2013). She subsequently obtained her PhD in physics from the group of Lilian Childress at McGill University on the topic of coupling atomic defects in diamond to microscopic optical cavities (2019). Currently, she is a postdoctoral researcher in the group of Christian Degen in the physics department of ETH Zurich, where she studies nanoscale NMR with diamond defects.

Konstantin Herb

Konstantin Herb holds a Bachelor's degree in Physics from the University of Stuttgart and a Master's degree in Physics from ETH Zurich. He worked on high-precision electron spin resonance and on high-resolution NMR spectroscopy using NV centers for his master thesis for which he was awarded an ETH Medal. During a research stay at the Martinos Center in Boston, he worked on the pre-clinical application of magnetic particle imaging. In 2020, he rejoined the Degen group as a PhD candidate and works on advanced quantum sensing methods for nanoscale NMR.

Laura A. Völker

Laura A. Völker holds both a Bachelor's and a Master's degree in Chemistry from ETH Zurich where she focused on the development and application of nuclear magnetic resonance (NMR) spectroscopy techniques in various fields of chemistry. In 2021 she joined the research group of Professor Christophe Copéret at ETH Zurich to study the surface organometallic chemistry of oxide materials using NMR spectroscopy. Since 2022, she is a PhD candidate

in the group of Professor Christian Degen researching chiral-induced spin selectivity using nitrogen-vacancy centers in diamond.

William S. Huxter

William S. Huxter received his BSc in engineering science in 2017 and his MSc in materials science and engineering in 2019 from the University of Toronto where he studied metal-semiconductor interfaces with scanning tunneling microscopy and density functional theory. In 2019 he joined the spin physics group of Christian Degen at ETH Zurich as a PhD candidate focusing on quantum sensing of magnetic and electric fields with scanning NV microscopy.

Christian L. Degen

Prof. Christian Degen joined the Department of Physics at ETH Zurich in 2011 after positions at MIT, Leiden University and IBM Research, Almaden. His background includes a PhD in magnetic resonance (Prof. Beat Meier) and postdoctoral training in scanning force microscopy (Dr Dan Rugar). Since 2009, he has led a research group on quantum sensing and nanomechanics.

John M. Abendroth

Dr John Abendroth earned his BSc in chemistry from the University of Florida and PhD in physical chemistry from the University of California, Los Angeles (Prof. Paul Weiss). His postdoctoral training was in materials science & engineering at Stanford University (Prof. Jennifer Dionne) and in physics at ETH Zurich (Prof. Christian Degen). Since 2021 he has been a senior researcher studying molecular systems using diamond-based quantum sensors.

progress toward mitigating these effects. Focus is given mainly to experiments on NV centers hosted in bulk diamond materials as opposed to scanning probe experiments and nanodiamonds, although, we note that many of the surface engineering techniques described here can be applied to those systems. Ultimately, applications in chemical sciences require precise and optimal placement of analytes on the diamond surface; we therefore highlight advances in chemical functionalization techniques that are compatible with near-surface NVs. This discussion is accompanied by a survey of measurement-based strategies for further improving detection sensitivities. Finally, we combine the aforementioned chemical toolbox and library of quantum control strategies to offer a perspective on untapped applications for NV-based quantum sensing of chemical systems.

2 Quantum sensing with the NV center

The NV center is the most widely used and best understood crystallographic defect in diamond.³² Its utility as a quantum sensor stems from a number of valuable properties: (i) atomic size, which provides nanoscale resolution, (ii) energetic coupling to a variety of physical quantities, (iii) long spin lifetimes (even at room temperature), (iv) coherent spin-state manipulation using microwave or optical fields, and (v) spin readout *via* spin-dependent fluorescence. In this section, we will introduce the NV center, discuss its basic sensing properties, and walk through several canonical sensing schemes with the goal of elucidating which sensor parameters are critical in the NV-sensing community.

2.1 Physical and electronic structure of the NV center

The NV center comprises a substitutional nitrogen atom and adjacent vacancy occurring along the $\langle 111 \rangle$ -family of crystallographic directions (Fig. 1a).¹⁶ Consequently, the NV center has threefold C_{3v} symmetry, where the z -axis is typically defined along the nitrogen–vacancy bond and the x -axis points orthogonally towards one of the three carbons closest to the vacancy. In its neutral state, five electrons contribute to the net electronic spin; one from each of the three carbon dangling bonds and two from the nitrogen lone pair.³³ When negatively charged by an additional electron, it develops a $S = 1$ spin character, which is essential for its use as a quantum sensor.¹⁶

The relevant low-energy states of the NV lie within the band gap of diamond, hosting an electronic ground-state ($|g\rangle$) with orbital-singlet, spin-triplet character (Fig. 1b). This state couples to the environment according to the ground-state Hamiltonian,^{16,35} which can be written as

$$\begin{aligned} \mathcal{H}_{\text{gs}} = & \underbrace{hD_{\text{gs}} \left(\hat{S}_z^2 - \frac{2}{3} \mathbb{1} \right)}_{\text{ZFS}} + \underbrace{\hbar\gamma_{\text{NV}} \vec{B} \cdot \vec{S}}_{\text{Zeeman}} + \underbrace{h \sum_{i=1}^M \vec{S} \mathbf{A}_i(\vec{r}_i) \vec{I}_i}_{\text{HFI}} \\ & + \underbrace{hd_z \mathcal{E}_z \left(\hat{S}_z^2 - \frac{2}{3} \mathbb{1} \right) + hd_{\perp} (\mathcal{E}_x (\hat{S}_y^2 - \hat{S}_x^2) + \mathcal{E}_y (\hat{S}_x \hat{S}_y + \hat{S}_y \hat{S}_x))}_{\text{Stark}}. \end{aligned} \quad (1)$$

Here, \hbar (\hbar) is the (reduced) Planck constant, $\vec{S} = [\hat{S}_x, \hat{S}_y, \hat{S}_z]$ are the spin-1 operators, \vec{I} is the nuclear spin operator and $\mathbb{1}$ is the identity operator. The simplified Hamiltonian in eqn (1) is spanned by the three $S = 1$ spin states: $|m_s = 0\rangle$, $|m_s = +1\rangle$, and $|m_s = -1\rangle$, and is grouped into four terms. First, there is a zero-field splitting (ZFS) term caused by electron spin–spin interaction, which shifts the $|m_s = \pm 1\rangle$ states in energy by $D_{\text{gs}} = 2.87$ GHz relative to $|m_s = 0\rangle$. The second term describes the Zeeman interaction for the $|m_s = \pm 1\rangle$ states, which is used to lift their degeneracy in quantum sensing experiments (Section 2.3); most commonly, the anisotropy of the interaction is neglected and the energy splitting is given by the product of the gyromagnetic ratio of the NV center γ_{NV} and the strength of the magnetic field. Here, the gyromagnetic ratio is $\gamma_{\text{NV}} = \gamma_e (1 + 357(74) \text{ ppm}) = 2\pi \times 28.0345(28) \text{ GHz T}^{-1}$ differing only slightly from the free electron value as typical for carbon-based materials.^{36–38} The third term of \mathcal{H}_{gs} includes coherent coupling to M proximal nuclear spins *via* the hyperfine interaction (HFI). The hyperfine tensor $\mathbf{A}_i(\vec{r}_i)$ comprises a dipolar component and a contact contribution for nearby nuclear spins. Finally, the fourth term describes the coupling to both electric fields \vec{E} and strain $\vec{\sigma}$, $\vec{\mathcal{E}} = \vec{E} + \mathbf{d}\vec{\sigma}$, which impact the NV center through electric dipole interaction, spin–spin interaction, and piezoelectric coupling (described by the tensor \mathbf{d}), all of which distort the electron orbitals.^{35,39,239} Consequently, the three-dimensional structure (and C_{3v} symmetry) of the NV necessitates a directional dependence on $\vec{\mathcal{E}}$. The coupling is mediated *via* the ground-state electric susceptibility parameters of the NV center $d_z = 3.5 \times 10^{-3} \text{ Hz (V m}^{-1}\text{)}^{-1}$ ⁴⁰ and $d_{\perp} = 0.165 \text{ Hz (V m}^{-1}\text{)}^{-1}$.⁴¹ An additional perpendicular electric term (proportional to the coupling parameter d'_{\perp}) is omitted from eqn (1), as it can be ignored when $d'_{\perp} \sqrt{\mathcal{E}_x^2 + \mathcal{E}_y^2} \ll D_{\text{gs}}$,³⁵ which is the case in most experiments.

In addition, the NV center is optically addressable, with an excited state ($|e\rangle$, Fig. 1b) located 1.945 eV (637 nm) above the ground state. This state has spin-triplet, orbital-doublet character (see other reviews for a detailed description^{16,32,42,43}) resulting in a fine structure containing six energy levels, which can be resolved under cryogenic conditions ($T < 10 \text{ K}$).⁴⁴ At elevated temperatures, these orbitals undergo rapid averaging caused by the dynamic Jahn–Teller effect,^{44,45} resulting in an effective three-level (spin-triplet) system at room temperature. In either case, decay from the NV excited state exhibits spin-dependent fluorescence (discussed in Section 2.2) that is exploited for spin-state readout in most NV-based quantum sensing schemes.

2.2 Photophysics and sensing properties

An ideal quantum sensor would offer mechanisms for coherent control of the sensor state, as well as methods for efficient state preparation and readout. Such a system can be realized within the NV ground state using the $m_s = 0$ and one of the $m_s = \pm 1$ states (hereafter generalized as $|0\rangle$ and $|1\rangle$, Fig. 1b) by applying a magnetic field along the z -axis to split the $m_s = \pm 1$ energy levels (see Fig. 1d). Impressively, resonant microwave fields

Fig. 1 The NV center. (a) Crystallographic structure. (b) Simplified NV electronic structure including ground-state fine structure. (c) NV low-temperature emission spectrum. (d) Continuous-wave optically detected magnetic-resonance (CW ODMR) measurements corresponding to different on-axis DC magnetic fields (B_0). Continuous optical and microwave excitation is applied to the NV and the microwave frequency is scanned across ground-state splitting. Dips in fluorescence with contrast C appear when the microwave frequency is resonant with the transitions between $m_s = 0$ and $m_s = \pm 1$. (e) Transient (time-resolved) spin-dependent fluorescence measurements for an NV center prepared in either the $m_s = 0$ or $m_s = -1$ spin states. (c) Adapted from ref. 34, Copyright 2006 Wiley-VCH Verlag GmbH & Co. KGaA.

have been used to achieve universal quantum control within the ground-state manifold¹³ with fidelities exceeding 99%.⁴⁶

Furthermore, the NV center optical transitions can be leveraged for initializing and reading out the spin state.^{13,47} Excitation to the excited state is typically achieved using an off-resonant laser (usually ~ 532 nm, see green arrows in Fig. 1b). The resulting NV fluorescence spectrum (radiative decay from the excited state to the ground state) comprises a zero phonon line (ZPL, 3% of emission)⁴⁸ and a broad phonon sideband (PSB, 97% of emission) that extends to 800 nm⁴⁹ (see red arrow in Fig. 1b and c). Such off-resonant schemes allow for spin preparation and readout using an intermediate singlet state ($|s\rangle$, see Fig. 1b): $m_s = \pm 1$ spin projections are more likely to decay non-radiatively from the excited state into $|s\rangle$, from which there is a roughly equal probability to decay (non-radiatively) to any spin projection in the ground state (grey arrow in Fig. 1b).^{50,51} Consequently, continuous 532 nm optical illumination results in a net ground-state spin polarization into $m_s = 0$.⁵⁰ Such spin polarization is illustrated in Fig. 1e, where both spin states reach the same fluorescence levels after ~ 1 μ s of laser excitation. Moreover, this non-radiative decay process provides a readout mechanism for the spin state since it yields reduced fluorescence for $m_s \pm 1$ states with up to $\sim 40\%$ contrast (Fig. 1d and e).⁵² The simplest experiment demonstrating this phenomenon is continuous-wave optically detected magnetic resonance (CW ODMR), in which microwave and laser excitation are applied simultaneously. When the microwave frequency is resonant the splittings between $|m_s = 0\rangle$ and $|m_s = \pm 1\rangle$, population is transferred and a reduction in fluorescence is observed (Fig. 1d).

The aforementioned preparation, control, and readout mechanisms for the NV offer a powerful toolbox for detection

of environmental signals. In practice, sensing applications benefit from several additional experimental constraints: (i) proximity to the sensing target for increased signal and spatial resolution, (ii) long measurement times for maximizing signal integration and spectral resolution, and (iii) efficient mechanisms for spin preparation and readout of the sensor. In the following, we describe relevant sensing properties that are directly influenced by these experimental constraints.

First, we note that the signal strength and detection volume of an NV sensor scales sensitively with experimental geometry, namely with the NV–target distance d . Indeed, for high-spatial-resolution detection of rapidly decaying signals, this distance must be minimized through both the NV–interface distance and the interface–target distance. Thus, there has been significant effort toward deterministic fabrication of near-surface NVs for sensing applications, which are outlined in Section 3.1. Furthermore, diamond surface functionalization methods yielding minimal stand-off distance are discussed in detail in Section 4.

The sensor spatial resolution is parameterized by the NV sensing volume, which depends on the specific protocol used and the NV orientation,⁵³ and scales as $V = (0.98d)^3$ for a (100)-terminated diamond. Fig. 2 shows an example sensitivity profile for an echo-like variance detection scheme (protocol details in Section 2.3). The regions outlined in black contribute 50% of the B_{rms}^2 signal (or equivalently 70% of B_{rms}) for a monolayer of spins on the diamond surface. The specific details of the sensing scheme play an important role, e.g., for phase canceling effects. In general, such sensitivity maps can be obtained by numerically evaluating the signal contribution of a single spin at every location of the diamond surface for a given measurement protocol. In addition, these maps vary

Fig. 2 Simulated sensitivity profiles for variance detection of surface spins with different NV orientations. These plots display B_{rms}^2 (in arbitrary units) for an NV at depth $d = 1$ below the diamond surface, where all length scales are normalized to this quantity. The areas enclosed with black lines in (b), (d), and (f) contribute 50% of the integrated B_{rms}^2 signal for an infinitesimally thin 2D layer of surface spins. Note that only fluctuations perpendicular to the NV axis were considered.

strongly with the NV-center crystallographic orientation and cut of the diamond (the surface plane), motivating careful consideration of the substrate.⁵³

Next, the measurement time T_m impacts signal integration and spectral resolution, and is fundamentally limited by the spin lifetimes of the NV center (either T_1 , T_2^* or T_2 depending on the measurement sequence). The largest of these values is the spin-lattice relaxation lifetime T_1 (also known as the longitudinal relaxation lifetime), which characterizes the time for the spin population to reach thermal equilibrium. Impressively, spin-lattice relaxation times within the ground-state manifold can reach a few milliseconds at room temperature⁵⁴ and hours at 4 K.⁵⁵ In contrast, T_2^* and T_2 refer to the transverse relaxation or spin-coherence lifetimes, which are theoretically limited to $2T_1$ although they are typically much shorter. T_2^* refers to the DC coherence decay time and T_2 is used to indicate general, pulsed (AC) coherence decay times. Spin-coherence

times of $T_2 > 1$ ms at room temperature⁵⁶ and $T_2 \sim 1$ s at 4 K⁵⁵ have been achieved using multi-pulse experiments (see Section 5). In practice, low-frequency noise leads to faster dephasing, resulting in $T_2^* \ll T_2$, which limits the ability to measure DC signals.

Furthermore, the spectral resolution Δf is an additional consideration for signals that may exhibit closely spaced resonances, such as detection of small chemical shifts, hyperfine couplings, or even spurious harmonics.^{57,58} For relatively simple sensing protocols, such as those described in the following section, Δf is limited by the coherence lifetime of the NV center and sensing protocol ($\Delta f \sim 1/T_2$). However, frequency resolution can be made arbitrarily small^{59,60} and it is possible to decouple the NV coherence time such that resolution is only constrained by the target spin coherence time,^{61,62} which can be significantly longer (see Section 5).

Next, the magnetic-field sensitivity improves for increased spin initialization fidelity. Off-resonant, optical spin polarization efficiency for deep NV centers depends on the applied laser power and can approach $\sim 80\%$.⁵⁰ However, we note that this value can vary considerably for shallow defects due to charge instability.³¹ Promisingly, logic-based charge initialization (of the negative NV^- state, see Section 3.2.1) has been employed to increase the average spin initialization fidelity of near-surface defects, with values approaching unity.³¹ Consequently, we ignore this quantity in subsequent calculations.

Finally, the readout fidelity F quantifies the ability to measure the spin state of the NV at the end of a single experiment, with $F = 1$ corresponding to an ideal, single-shot readout. This value varies considerably for different experimental conditions, and is therefore explored extensively in this text. Since quantum sensing experiments often employ repeated measurements for statistical averaging, a larger readout fidelity can speed up experiments significantly. For off-resonant readout, the fidelity is given by^{63,64}

$$F = \left(1 + 2 \frac{(\alpha_0 + \alpha_1)}{(\alpha_0 - \alpha_1)^2} \right)^{-1/2}, \quad (2)$$

where α_0 and α_1 are the expected number of measured photons for $|0\rangle$ and $|1\rangle$, respectively. Here, $\alpha_1 = (1 - C)\alpha_0$, where C is the measurement contrast. Moreover, $\alpha_0 = \xi\gamma T_R/(2\pi)$, where ξ is the photon collection efficiency, γ is the radiative decay rate (expressed here as an angular frequency), and T_R is the readout time, yielding

$$F = \left(1 + 4\pi \left(\frac{2 - C}{C^2 \gamma \xi T_R} \right) \right)^{-1/2}. \quad (3)$$

Typical off-resonance fidelities are quite poor ($F \sim 0.03$)⁶³ and much experimental work has been directed at increasing these values (details in Section 2.6).

2.3 Magnetic sensing

The vast majority of NV sensing focuses on magnetic interactions owing primarily to its strong coupling constant (γ_{NV}), which impacts detection of external fields as well as the

strength of the (dipolar) hyperfine interaction. In the following section, we will explore the sensitivities obtained for some of the simplest detection protocols, including DC and AC schemes with the Ramsey and spin-echo experiments, as well as T_1 and T_2 relaxation experiments. While these represent only a small fraction of possible sensing schemes, they illustrate which experimental parameters should be considered and optimized when implementing an NV sensor.

For these examples, we simplify eqn (1) to include only contributions related to a small, time-dependent magnetic field $\vec{B}(t)$ and a relatively large magnetic-field bias B_0 along the z -axis of the NV center, yielding

$$\mathcal{H}_{\text{gs}} = \hbar D_{\text{gs}} \hat{S}_z^2 + \hbar \gamma_{\text{NV}} (B_0 + B_z(t)) \hat{S}_z. \quad (4)$$

Note that eqn (4) is only accurate in the limiting case where $\hbar \gamma_{\text{NV}} B_i(t) \ll \hbar D_{\text{gs}}$ and $B_i(t) \ll B_0$ for $i = \{x, y, z\}$, such that the NV center becomes insensitive to $B_x(t)$ and $B_y(t)$. The transition energies (e_{\pm}) between the $m_s = 0$ and $m_s = \pm 1$ spin levels are then

$$e_{\pm} = \hbar D_{\text{gs}} \pm \hbar \gamma_{\text{NV}} (B_0 + B_z(t)). \quad (5)$$

In this Review, we consider a simplified sensor utilizing a two-level subspace spanned by the $|m_s = 0\rangle$ and one of the $|m_s = \pm 1\rangle$ states, resulting in the following effective Hamiltonian

$$\mathcal{H}_{\text{gs}} = \hbar \gamma_{\text{NV}} B_z(t) \hat{S}_z. \quad (6)$$

Here, a rotating frame was used to remove the contributions from D_{gs} and B_0 . We note that an alternative effective Hamiltonian yielding twice the signal can be obtained by instead using the subspace spanned by the two $|m_s = \pm 1\rangle$ states (details in Section 5.4). The basic sensing premise is as follows: first, the NV state $|\psi\rangle$ is initialized to $|0\rangle$ via optical pumping; subsequently, a

superposition state $|\psi(t=0)\rangle \propto |0\rangle + |1\rangle$ is created through the application of a $(\pi/2)_y$ rotation (e.g., with a microwave pulse), which can be visualized on the Bloch sphere⁶⁵ (Fig. 3). While $|0\rangle$ and $|1\rangle$ are eigenstates of eqn (6), superposition states are not and will therefore evolve in time. In particular, $|0\rangle$ and $|1\rangle$ will acquire a relative phase ($|\psi(\tau)\rangle \propto |0\rangle + e^{i\phi(\tau)}|1\rangle$) that is a function of the applied magnetic field

$$\phi(\tau) = \gamma_{\text{NV}} \int_0^{\tau} B_z(t) dt, \quad (7)$$

where τ is the total evolution time. $|\psi(\tau)\rangle$ will remain in an equal superposition (with equal population in $|0\rangle$ and $|1\rangle$) for all values of ϕ ; however, NV fluorescence can only be used to measure the state populations and not coherences. Application of a second $(\pi/2)_y$ rotation can convert ϕ into a population difference, which can be read out via spin-dependent fluorescence. By comparing the resulting fluorescence level against that of the $|0\rangle$ and $|1\rangle$ states, one can infer ϕ through the transition probabilities $p_0 = \sin^2(\phi/2)$ or $p_1 = \cos^2(\phi/2)$, respectively, for the sensing scheme shown in Fig. 3a. Equivalently, p_i is the expectation value of being in state $|i\rangle$ after the last $(\pi/2)_y$ rotation. Typically, one characterizes the magnetic field by measuring the deviation of the transition probability $\delta p = p_i - p$, where p is some fixed bias point. If the measurement protocol can be synchronized with the target signal, the highest sensitivity is obtained for “slope detection”,^{61,63} wherein $p = 0.5$ (corresponding to an equal superposition) or $\phi = k\pi/2$ for odd integers k . In the small signal limit ($\delta\phi \ll \pi$), this yields $\delta p = \delta\phi/2$ (for $k = 1$). However, many experimental applications preclude synchronization with the signal of interest, resulting in $\langle \delta p \rangle = \langle \delta\phi \rangle = 0$ for multiple measurements. In such cases, it is beneficial to instead apply “variance detection”,^{66–68} wherein the system is biased at $p = 0$

Fig. 3 Ramsey and spin-echo sensing experiments. (a) Pulse sequences for the Ramsey and the Hahn-echo protocols. Laser pulses are indicated in green, microwave manipulations are shown in yellow, and phase evolution periods are shaded in grey. (b) Bloch-sphere evolution throughout a Ramsey experiment, (c) Bloch-sphere evolution throughout a spin-echo experiment (steps 1–3 are identical to those of the Ramsey sequence).

and the variance in transition probability $\langle \delta p^2 \rangle = \frac{1}{4} \langle \delta \phi^2 \rangle = \frac{1}{4} \phi_{\text{rms}}^2$ is measured.

The SNR of slope-detection-based experiments is defined as $\text{SNR} = \delta p / \sigma_p$, where $\sigma_p = 1 / (2\sqrt{NF})$ is a combination of the quantum projection noise for N experimental repetitions and the classical readout noise associated with the finite readout efficiency (described by F).¹⁰

This analysis can be applied directly in determining the sensitivity of the Ramsey experiment,⁶⁹ which is one of the simplest methods for determining a DC magnetic field of the form $B_z(t) = B_{\text{DC}}$. Following eqn (7), such a field would result in an acquired phase of $\phi(\tau) = \gamma_{\text{NV}} B_{\text{DC}} \tau$ (Fig. 3a). Subsequent conversion to NV population followed by slope detection yields $\delta p = \gamma_{\text{NV}} \tau \delta B_{\text{DC}} / 2$ with $\text{SNR} = \gamma_{\text{NV}} F \delta B_{\text{DC}} \sqrt{\tau T}$ for a total experiment duration $T = N\tau$. The sensitivity can then be calculated as $\eta_{\text{DC}} \approx 1 / (\gamma_{\text{NV}} F \sqrt{\tau})$, which is optimized by maximizing the acquisition time τ . For the Ramsey experiment, τ is fundamentally limited to the natural dephasing time of the sensor spin T_2^* , resulting in a minimum sensitivity of

$$\eta_{\text{DC}} \approx 1 / (\gamma_{\text{NV}} F \sqrt{T_2^*}). \quad (8)$$

While Ramsey experiments are ideal for sensing DC fields, they are ill-suited for detection of signals that vary quickly compared to τ since the acquired phase is averaged away over the course of the measurement. For detection of AC magnetic fields, the canonical *spin-echo* experiment⁷⁰ incorporates an intermediate (π)_y pulse (Fig. 3b) that flips the spin, allowing for an effective reversal of the detected field $B_z(t)$ according to

$$\phi_{\text{echo}}(\tau) = \gamma_{\text{NV}} \int_0^{\tau/2} B_z(t) dt - \gamma_{\text{NV}} \int_{\tau/2}^{\tau} B_z(t) dt. \quad (9)$$

We consider a magnetic field with frequency ω and phase θ described by $B_z(t) = B_{\text{AC}} \sin(\omega t + \theta)$; if θ is known, slope detection can be employed, yielding

$\phi_{\text{echo}} = -\frac{4B_{\text{AC}}\gamma_{\text{NV}}}{\omega} \cos(\omega\tau/2 + \theta) \sin^2(\omega\tau/4)$. This quantity is maximized for $\omega = 2\pi/\tau$ and $\theta = 0$, resulting in $\phi_{\text{echo}} = 2B_{\text{AC}}\gamma_{\text{NV}}\tau/\pi$. The sensitivity can then be calculated as

$$\eta_{\text{AC}} \approx \pi / (2\gamma_{\text{NV}} F \sqrt{T_2}). \quad (10)$$

Here, we set $\tau = T_2$ where T_2 is the spin-echo coherence time. This protocol has the added benefit of cancelling low-frequency noise occurring on timescales slower than τ ; consequently T_2 often far exceeds the natural decoherence time T_2^* , resulting in an improvement in slope-detection sensitivity of $\eta_{\text{DC}}/\eta_{\text{AC}} \approx \sqrt{T_2/T_2^*}$.

Similarly, the sensitivity for variance detection of an AC field can be calculated from $\phi_{\text{rms}} = \sqrt{2}B_{\text{AC}}\gamma_{\text{NV}}\tau/\pi$ and $\text{SNR} = \langle \delta p^2 \rangle / \sigma_p$ resulting in

$$\eta_{\text{var}} \approx \pi / (\gamma_{\text{NV}} \sqrt{F} \sqrt{T_2^3}). \quad (11)$$

Complementing these widely used DC and AC measurement techniques, *relaxometry*^{71,72} offers a sensing modality for detecting magnetic and electric noise at $\omega_{01} = e_{\pm}/\hbar$, the frequency

splitting between $|m_s = 0\rangle$ and $|m_s = \pm 1\rangle$. While the Ramsey and spin-echo protocols operate in the 0 Hz (DC) to <1 GHz regimes, ω_{01} may exist in the few GHz regime, extending the frequency range over which NV sensors can be employed.^{73,74}

In such experiments, the system is initialized to $|0\rangle$ and allowed to evolve for time τ . Subsequently, δp is measured, displaying an exponential decay as a function of time with rate

$$\Gamma_1 = \frac{1}{T_1} = \frac{\gamma_{\text{NV}}^2}{2} S_{B,\perp}(\omega_{01}). \quad (12)$$

Here, $S_{B,\perp}(\omega)$ is the power spectral density of the transverse magnetic field,¹⁰ which appears since perpendicular magnetic fields induce spin flips resulting in T_1 relaxation. In addition, relaxometry involving high-frequency noise related to electric fields has also been demonstrated.^{75,76} If the system is instead prepared in a superposition state $|\psi(t=0)\rangle \propto |0\rangle + |1\rangle$ then the associated decay time also depends on the parallel component of the noise spectral density $S_{B,z}(\omega)$, yielding

$$\Gamma_2 = \frac{1}{2T_1} + \frac{1}{T_2^*} = \frac{\gamma_{\text{NV}}^2}{4} S_{B,\perp}(\omega_{01}) + \frac{\gamma_{\text{NV}}^2}{2} S_{B,z}(0), \quad (13)$$

where $S_{B,z}$ is probed at $\omega = 0$ since phase flips do not require energy.¹⁰ Typically, $T_1 \gg T_2^*$ such that $\Gamma_2 \approx 1/T_2^*$, yielding the natural dephasing time observed in Ramsey experiments. Indeed, this decay rate can be thought of in terms of the rms phase previously mentioned in the context of variance detection, where $\phi_{\text{rms}}^2 = 2\Gamma\tau$. Moreover, extension of this technique with multi-pulse sequences (such as spin-echo or the dynamical decoupling sequences described in Section 5) enable measurements of $S_{B,z}$ for non-zero ω .^{77,78}

2.4 Electric sensing

Electric-field sensing with NV centers is possible through a piezoelectric coupling that produces a Stark shift in the NV resonance levels.^{32,35,39,79} While such schemes suffer from poor sensitivities (in comparison to magnetic detection), bulk and surface charge screening,^{80,81} and complications from strain interactions, electric-field sensing may prove useful for the chemical sciences. For example, the NV is capable of detecting surface electrons in this manner^{75,76} and has enabled the mapping of a single electron *via* its electric field from a distance of roughly 25 nm.⁸² Consequently, improved surface preparation techniques may enable sensing of electrons involved in various chemical processes. Additionally, measurements of local strain⁸³ and local band bending⁸⁰ would inform the fabrication of stable and shallow NV centers. Furthermore, electric-field sensing could complement magnetic sensing of surface molecules, providing a route to disentangle signal contributions from magnetic fields (arising from electron spins and currents) and electric fields (due to electron charge).

An electric-field sensor can be realized using a single energy-level transition (Section 2.3) with a sensitivity defined similarly to those of magnetic-field protocols where the electric susceptibility parameters (d_z and d_{\perp}) serve the same purpose as the gyromagnetic ratio (γ_{NV}). With established techniques for sensing DC and AC electric fields with deeply implanted NV

centers,^{41,84,85} current research efforts are focused on nano-scale sensing of external electric fields with shallow NV centers.^{86–88}

In this section, we will highlight two common sensing schemes for measuring electric fields. Both schemes derive from a second order perturbation theory under the assumption of $\hbar\gamma_{\text{NV}}B_i \ll \hbar D_{\text{gs}}$ and neglecting nuclear spin coupling.^{35,84} For simplicity, we also ignore contributions from strain; however, we note that in the high-strain limit ($|\vec{\sigma}| \gg |\vec{E}|$), electric-field sensing is only possible along the strain direction.

The first scheme for electric-field sensing requires a weak magnetic bias field along the z-axis of the NV center ($B_0 = B_z$). In the presence of an electric field, the transition energies are

$$e_{\pm}(B_z, \vec{E}) = e_{\pm}(B_z) + \hbar d_z E_z(t) \pm \frac{\pi \hbar d_{\perp}^2}{\gamma_{\text{NV}} B_z} E_{\perp}^2(t), \quad (14)$$

where $e_{\pm}(B_z)$ is the contribution from the ZFS and bias field (eqn (5)) and $E_{\perp}^2(t) = E_x^2(t) + E_y^2(t)$. By applying sufficiently large B_z , it is possible to isolate the E_z component of the field.⁷⁵

The second scheme employs a weak perpendicular magnetic bias field ($B_0 = B_{\perp} = (B_x^2 + B_y^2)^{1/2}$) on the NV center. In this configuration, the transition energies are

$$e_{\pm}(B_{\perp}, \vec{E}) = e_{\pm}(B_{\perp}) + \hbar d_z E_z(t) \mp \hbar d_{\perp} E_{\perp}(t) \cos(2\varphi_B + \varphi_E), \quad (15)$$

where $e_{\pm}(B_{\perp})$ includes the contribution from the ZFS and a nonlinear shift from B_{\perp} . The additional cosine term involving two in-plane angles ($\tan \varphi_B = B_y/B_x$ and $\tan \varphi_E = E_y(t)/E_x(t)$) allows for control over the electric-field detection axis through variation of φ_B .⁸⁴ Since $d_{\perp}/d_z \sim 47$, this detection scheme is significantly more sensitive to perpendicular electric fields; consequently, the E_z term is often excluded for simplicity.

2.5 Additional sensing modalities

The NV center is susceptible to additional physical quantities through the dependencies of the Hamiltonian coupling terms; for example, the ZFS splitting is both a function of temperature and pressure ($D_{\text{gs}}(T, P)$).^{89,90} Consequently, careful attention must be taken to correctly attribute energy-level shifts that occur under non-ambient experimental conditions, *e.g.*, elevated temperatures or pressures required for specific reactions or temperature changes resulting from exothermic and endothermic reactions.

Lastly, it is also possible to utilize the excited-state coupling terms, which can greatly differ from those found in the ground-state Hamiltonian.^{16,39} Of particular note, the excited-state electric susceptibility parameters are much larger than those of the ground state, enabling significantly more sensitive electric-field detection.⁹¹ However, such techniques employ resonant optical pumping that is only possible at cryogenic temperatures, precluding general use.⁹¹

2.6 Experimental considerations

As an illustrative example, we explore the experimental considerations for the detection of a single nuclear spin external to the diamond using variance detection. The magnitude of the magnetic variance generated by the Larmor precession of a single nuclear spin at distance d from the NV is²⁴

$$B_n^2 \approx \frac{(\mu_0 \hbar \gamma_n)^2}{16\pi^2 d^6}, \quad (16)$$

where μ_0 is the vacuum permeability and γ_n is the gyromagnetic ratio of the nuclear spin. Following the calculations in Section 2.3, the minimum detectable variance after N repetitions of the spin-echo experiment is

$$\delta B^2 = \frac{\pi^2}{\gamma_{\text{NV}}^2 T_2^2 F \sqrt{N}}, \quad (17)$$

and the expected number of detectable nuclear spins is

$$N_{\text{nuc}} \approx \frac{\delta B^2}{B_n^2} = \left(\frac{4\pi^2}{\gamma_{\text{NV}} \gamma_n \hbar \mu_0} \right)^2 \frac{d^6}{T_2^2 F \sqrt{N}}. \quad (18)$$

The contributions of parameters d , T_2 , F , and N allow us to identify potential avenues for minimizing N_{nuc} , ideally approaching the single-spin regime of $N_{\text{nuc}} = 1$.

Eqn (18) scales with the sixth power of d , emphasizing the crucial importance of minimizing the NV-target distance. While the exact dependence of the magnetic-field strength on d varies for different target geometries ($B_{\text{rms}}^2 \sim 1/d^6$ for a single spin, $B_{\text{rms}}^2 \sim 1/d^4$ for a two-dimensional spin layer, and $B_{\text{rms}}^2 \sim 1/d^3$ for a volume of spins),^{24,66,92} reducing this distance will always result in a larger field at the NV.

Eqn (18) also illustrates the effect of extending T_2 , which has inspired large bodies of work aimed at fabricating coherent, near-surface emitters (Section 3) in addition to development of sensing protocols for extending T_2 by mitigating surface noise (Section 5).

Finally, improving the readout fidelity is another avenue for experimental optimization. For off-resonant excitation, the readout fidelity is limited by short readout times ($T_R \approx 400$ ns) due to the transient nature of the spin contrast (Fig. 1e), the low radiative emission rate of the NV ($\gamma = 2\pi \times 13$ MHz), and poor optical collection efficiency ($\xi \sim 0.01$ is typical for confocal measurements of bulk diamond). Such schemes are further limited for $C < 1$, resulting in an overall readout fidelity of only $F \sim 0.03$ (eqn (2) and (3)). For such a low value, more than 500 experimental repetitions would be required to achieve $\text{SNR} = 1$. Encouragingly, several routes have been explored to increase off-resonant readout fidelity, including nuclear-spin-assisted techniques (obtaining $F = 0.5$)²⁴ and spin-to-charge conversion⁹³ with near-unity fidelity ($F > 0.99$).⁹⁴ However, such protocols come at the expense of additional experimental overhead and significantly longer readout times.

The best combination of NV preparation and readout fidelities have been achieved using resonant excitation of spin-dependent optical transitions within the ZPL.⁹⁵ Below 10 K, the ZPL transitions of such emitters can be spectrally resolved and

optically cycled multiple times before spin flips occur. This cyclicity allows for spin-state readout *via* excitation and the subsequent presence or absence of corresponding emission, yielding $F = 0.97$.^{96,97} Meanwhile, a small degree of spin mixing within the excited state is used as a resource for spin preparation *via* resonant optical pumping, yielding near-perfect preparation efficiencies (99.8% into $m_s = 0$).⁹⁶ These techniques have been combined to demonstrate imaging of a 27-spin ^{13}C cluster within a diamond substrate at cryogenic temperatures.⁹⁸ Finally, access to resonant optical transitions can facilitate all-optical spin manipulation,⁹⁹ albeit with substantially lower fidelity than microwave techniques due to spontaneous emission. Unfortunately, this set of techniques have largely relied on the exceptional optical stability of naturally occurring NV centers located microns below the diamond surface.¹⁰⁰ Indeed, resonant excitation of near-surface NV centers is not possible due to instability of the ZPL frequency over time referred to as spectral diffusion.^{101,102} The asymmetry of the nitrogen and vacancy sites (Fig. 1a) leads to inequivalent electric dipole moments in the ground and excited states, which makes it extremely sensitive to electric-field noise on nearby surfaces. Such noise can cause spectral diffusion of the optical transition of many GHz,⁴²⁵ precluding spectral selectivity within the ZPL fine structure. Consequently, near-surface NV centers required for studying external targets rely on off-resonant excitation.

We conclude by noting that chemical sensing at diamond surfaces may be performed using either single NV centers or ensembles of shallow defects. Single emitters boast nanoscale spatial resolution but are limited in signal by their radiative emission rate γ and optical collection efficiency ξ .^{63,103} A reduction in excited-state lifetime can be achieved *via* coupling to an optical resonator structure,¹⁰⁴ while higher optical collection efficiencies can be obtained using nanophotonic structures such as waveguides, lenses, cavities, or gratings.^{95,105–114}

In contrast to single NV sensors, dense ensembles offer accelerated measurement times that scale with N_{NV} , the number of NVs.¹⁰ Moreover, the sensitivity scales with $\sqrt{N_{\text{NV}}}$ per unit time,¹⁰ with a best predicted sensitivity of *ca.* 250 aT Hz^{-1/2} cm^{-3/2} in the high-density limit.⁶³ Higher

density, however, may be accompanied by reduced coherence times that ultimately limit sensor utility.^{103,115} Furthermore, the efficient collection of fluorescence from ensembles of NV centers remains difficult; some nanofabricated structures that offer improvement for single NVs may not be suitable for ensembles. Still, alternative strategies that rely on absorptive and dispersive schemes could improve light collection from ensembles.^{116–119} Finally, we note that nanostructured diamond surfaces hosting high NV densities benefit from increased sensor–analyte contact area.¹²⁰

3 Surface influence on NV center stability

Achieving the excellent magnetic-field sensitivity and spatial resolution required for detecting single molecules necessitates shallow NV centers (*i.e.*, depths < *ca.* 10 nm). Unfortunately, emitter optical and spin properties deteriorate within *ca.* 100 nm of the diamond surface,³⁰ presenting a critical challenge. In this section, we introduce how shallow NV centers are typically generated and then detail the leading sources of their charge instability and spin dephasing (summarized in Fig. 4). Finally, we describe suitable surface terminations that have been theoretically and experimentally identified to promote preservation of NV center properties.

3.1 Generation of shallow NV centers

Magnetic sensing of external targets necessitates fabrication processes that yield a deterministic density of shallow NVs with high spin coherence.¹²¹ Most commonly, NV-forming nitrogen atoms are incorporated into electronic-grade diamond through post-growth, blanket implantation,^{122–124} forming a randomly distributed, two-dimensional layer of impurities at a depth and density determined by the acceleration energy and fluence, respectively.¹²⁵ In contrast, deterministic impurity placement can be achieved by performing implantation with a focused ion beam (FIB),^{126–129} or through a mask.^{130–133} In fact, a combination of shallow masked implantation and diamond

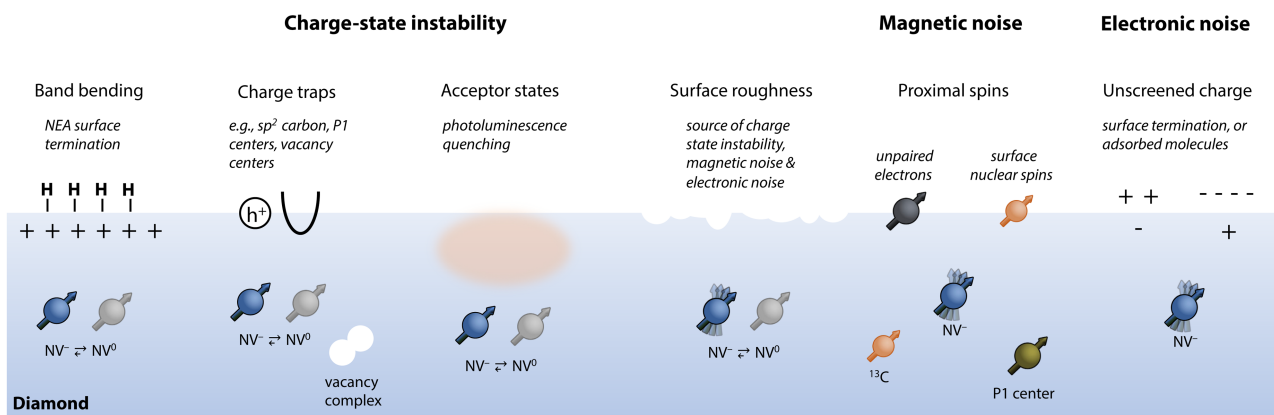

Fig. 4 Summary of sources of charge-state instability and decoherence for near-surface NV centers.

overgrowth has been used to achieve high-precision placement for alternative defect centers.¹³⁴ Subsequent high-temperature, high-vacuum annealing (*ca.* 800–880 °C) mobilizes vacancies created by implantation, which combine with nitrogen to form NV centers with varying efficiency.^{123,135–137} Unfortunately, the implantation and annealing processes can lead to formation of unwanted vacancy complexes that degrade coherence. This effect increases with implantation energy, but there is evidence that annealing at higher temperatures (*i.e.*, 1000–1500 °C) can eliminate localized defects that degrade the spin and optical properties of emitters.^{138–141} Furthermore, Fermi-level engineering through co-doping with donor impurities may preclude the formation of vacancy chains.¹⁴²

An alternative strategy for defect formation is impurity incorporation during diamond growth *via* chemical vapor deposition (CVD) or high-pressure, high-temperature (HPHT) synthesis. In both cases, NV centers can be formed naturally from non-negligible native nitrogen levels. However, such defects occur at random positions within the diamond crystal, limiting their utility. In HPHT synthesis, higher nitrogen content is typically observed (up to hundreds of ppm) than during CVD growth, with varying densities related to the efficiency of nitrogen incorporation along different crystallographic growth directions.^{143,144} Conversely, nitrogen incorporation during CVD growth can localize emitters into a single growth layer (referred to as delta doping).^{145–149} Advantageously, deterministic introduction of nitrogen during the CVD growth process can allow for preferential alignment along one of the four possible crystallographic orientations.^{150–152} Such alignment is useful both for higher experimental throughput in single NV studies as well as for obtaining higher contrast in ensemble NV measurements. Following impurity incorporation, techniques such as electron irradiation,^{100,153–155} laser writing,^{156,157} or implantation with additional species^{153,158,159} can be used to generate the vacancies necessary for emitter formation through subsequent annealing.

3.2 Origins of instability

In this section, we explore physical phenomena leading to reduced measurement sensitivity for near-surface NV centers, namely charge instability and magnetic and electronic noise.

3.2.1 NV charge state conversion. The NV center has three physically relevant charge configurations comprising the negative (NV⁻), neutral (NV⁰), and positive (NV⁺) states. So far, only the long-lived, *S* = 1 ground state (see Section 2) of the negatively charged state has proven useful for quantum sensing applications. Indeed, the *S* = 1/2 ground state of NV⁰ is subject to line broadening caused by Jahn–Teller distortion that precludes EPR detection.¹⁶⁰ Moreover, the neutral charge state is also excited by green laser light (ZPL at 575 nm), contributing fluorescent background that reduces measurement contrast. Conversely, the positively charged NV⁺ state is expected to be spinless, and is traditionally treated as a dark state since no optical signature has been observed thus far.¹⁶¹ Proximity to surfaces can exacerbate dynamic or permanent switching to

other charge states,³¹ reducing the charge-state efficiency, defined as

$$\zeta = \frac{[\text{NV}^-]}{[\text{NV}^-] + [\text{NV}^0] + [\text{NV}^+]} \approx \frac{[\text{NV}^-]}{[\text{NV}^-] + [\text{NV}^0]} \quad (19)$$

While the NV⁰ state has garnered interest for super-resolution microscopy,^{162–164} optical data storage,^{166,167} quantum information processing,^{165,168–170} and as an electrically driven single-photon source,¹⁷¹ it contributes an undesirable background when probing NV⁻ centers for magnetic sensing; therefore, ζ should be maximized. However, due to unavoidable charge-state cycling between NV⁻ and NV⁰, the maximum achievable ζ is limited under normal measurement conditions.^{163,168}

Photoinduced charge conversion between the NV⁻ and NV⁰ states can occur *via* one-photon (energy > 2.6 eV) or two-photon (energy > 1.946 eV) absorption processes that eject an electron into the conduction band of diamond.¹⁶⁷ The reverse process, reduction of NV⁰ back to its negative state, may also occur *via* both one-photon (energy > 2.94 eV) or two-photon (energy > 2.156 eV) absorption processes by receiving an electron from the diamond valence band.¹⁶⁷ Consequently, green laser excitation that is commonly used for spin preparation and readout results in unavoidable modulation between NV⁻ and NV⁰, leading to a steady-state $\zeta \approx 0.75$.^{163,172,173} This value can be even smaller for NV ensembles,¹⁷⁴ where tunneling between proximal NV centers and nearby nitrogen species may occur upon photoexcitation.¹⁷⁵ Multicolor illumination with near-infrared light^{94,176,177} (resulting in spin-dependent charge transfer^{178,179}), doping,^{180–182} and high laser powers¹⁸³ provide possible routes to increase the relative population of NV⁻. Moreover, spin-dependent ionization of NV⁻ *versus* NV⁰ states has been used as a resource for achieving single-shot spin readout.^{93,94,184}

Proximal surfaces preferentially convert NV⁻ to NV⁰ following photoionization since local electronic traps and acceptor states inhibit electron exchange between the NV and the diamond electronic bands (Fig. 4).^{31,185} Moreover, charge-state instability has also been observed in the dark (without photoexcitation), which is hypothesized to occur by tunneling to electron traps.^{31,167,186} Such non-optical discharge of NV⁻ is exacerbated near surfaces, where primal sp² carbon serves as an efficient charge trap.^{81,187}

While it cannot account for all processes leading to NV-center destabilization,^{167,188,189} a band-bending model provides a simplified picture of how the NV⁻ state is affected by surface proximity.¹⁹⁰ An electric dipole layer at the surface, due to the terminating species or chemical adsorbates, can lead to accumulation of positive or negative charge at the diamond interface. In the case of hole accumulation, electrons are withdrawn from shallow NV centers, yielding the neutral charge state.^{191–193} This is captured by the electron affinity of the surface, defined as

$$\chi = E_{\text{vac}} - E_{\text{CBM}} \quad (20)$$

where E_{vac} and E_{CBM} are the energies of the vacuum level and conduction band minimum, respectively (Table 1). A negative electron affinity (NEA) surface, corresponding to upward bending of the valence and conduction bands, occurs when E_{CBM} is shifted above the vacuum level. Such bending is induced by the bond polarization at the surface when adsorbates of lower electronegativity than carbon are present. For instance, hydrogen-terminated diamond is known to exhibit NEA with $\chi = -1.3$ eV measured in vacuum, which depletes the electron density available for near-surface NV centers.^{194–197} Conversely, a positive electron affinity (PEA) surface occurs when the conduction band minimum lies below E_{vac} , and is generally desirable for stabilizing the NV^- state. In such cases, chemical terminations or adsorbates with higher electronegativity than carbon increase χ compared to that of a pristine diamond surface. Surface terminations that have been found to achieve PEA for NV sensing are described in detail in Section 3.3.

3.2.2 Magnetic and electronic noise. As discussed in Section 2.3, the best detection sensitivities are obtained by maximizing T_2 , which is hampered by unwanted noise. For near-surface NV centers, this noise comes from magnetic and electronic sources (Fig. 4), though decoherence of shallow emitters is primarily ascribed to magnetic noise.³⁰ Deleterious spin impurities occurring in the bulk crystal, such as substitutional nitrogen (P1) centers,²¹⁶ can be limited through use of ultra-pure diamond substrates; however, the surface is always problematic, regardless of substrate purity. Indeed, surface spins may generate considerable magnetic noise through spin flips and precession,^{217,218} leading to a reduction in NV-center T_1 and T_2 via dipole–dipole coupling. In both bulk materials^{78,92,219–224} and nanodiamonds,^{225–229} this magnetic noise may arise from surface nuclear spins, unpaired electrons in dangling bonds, surface adatoms, and molecular adsorbates. Moreover, spin-orbit interactions in sp^2 carbon, as well as potential biradical spin character or magnetization in mixed sp^2/sp^3 material, may also contribute.⁸¹

The influence of a surface spin bath on shallow NV centers can be exploited as a useful probe of the local chemical environment,^{230,231} which has been widely used for chemical and biochemical sensing with NV centers both in bulk diamond and nanodiamond systems. For example, relaxometry measurements that do not require microwave irradiation can be used to characterize changes in T_1 caused by *e.g.*, proximal paramagnetic species,²³² redox reactions,²³³ changes in pH,²³⁴ and radical production.^{235–237} Nevertheless, for highly sensitive techniques such as NMR spectroscopy, these sources of magnetic noise are often undesirable. Consequently, the optimization of diamond surface chemistries is a critical step toward realizing the full potential of NV sensing for dilute assemblies of external spins.

The influence of electric-field noise on the NV is thought to be comparatively minor,³⁰ unless operating in a regime where the NV EPR frequencies exhibit anticrossings²³⁸ or in an off-axis magnetic field.^{84,239,240} However, in some cases, electric noise has been shown to dominate magnetic noise. Indeed, Kim *et al.*

showed an almost factor-of-5 increase in T_2 for shallow NV centers when bare diamond surfaces were coated in dielectric liquid to shield fluctuating surface charges.⁷⁵ In contrast, the magnetic noise generated by dark spins was unaffected by the coating. In addition, Myers *et al.* used complementary double-quantum relaxometry measurements to differentiate between electric and magnetic noise sources, demonstrating that T_1 was limited by surface electric-field noise at low magnetic fields.²⁴¹

Moving forward, systematic investigations using multiple measurement techniques will be essential in optimizing surface preparations for attaching molecules of interest. For (bio)-chemical sensing, functionalization with dense, highly charged, and mobile biomolecules contributes additional sources of electric-field noise and may pose a challenge for highly sensitive measurements. One solution would be to operate at large magnetic-field strengths; in addition, dielectric surface layers (*e.g.*, solid- or solution-phase capping material) may mitigate electric-field-driven decoherence of shallow NV centers.^{75,242} Still, the choice of dielectric coating depends critically on the operational frequency range of the sensor²⁴² and its compatibility with the analytes of interest. An as-yet unexplored strategy to shield near-surface NVs from fluctuating electric fields could leverage surface dipole control using self-assembled monolayers (SAMs).^{243,244} More generally, magnetic and electric noise sources from surface traps could be reduced using highly homogeneous chemical surface functionalization, which is detailed in Section 4.

3.3 Surface terminations for increasing NV stability

Common diamond CVD growth employs hydrogen gas, resulting in hydrogen termination of dangling bonds at interfaces.^{245,246} This termination induces a highly unfavorable NEA that destabilizes the NV^- state. Furthermore, H termination is expected to introduce sub-bandgap states resulting in delocalization and loss of NV electrons upon photoexcitation.¹⁸⁹ While hydrogen termination will naturally degrade when exposed to air, the systematic chemical control of diamond surfaces offers a solution to combat destabilization of shallow NV centers.^{189,247} Below, we summarize methods for tailoring the diamond surface termination and explore the resulting influence on NV-sensing properties. Subsequent chemical functionalization with molecular films of interest is described in Section 4.

3.3.1 Fluorine surface termination. Halogen termination of diamond may occur naturally during CVD growth processes that employ halogenated carbon precursors, or by post-growth treatments including plasma exposure,^{248–250} electrochemical techniques,²⁵¹ atomic beams,²⁵² X-ray irradiation,²⁵³ and others.^{254–256} In particular, termination with fluorine has received considerable attention in the context of NV sensing; as the most electronegative element, fluorine is a promising surface termination for inducing PEA.¹⁹⁸ Moreover, the 100% natural abundance of the $I = 1/2$, ^{19}F isotope would enable its proposed use as a platform for nuclear-spin-based quantum simulation,²⁵⁷ further motivating its exploration.

Theoretically, fully fluorinated surfaces are expected to yield favorable PEA. For example, (100)-cut diamonds, which are most commonly used, are estimated to have $\chi = 2.13\text{--}3.00$ eV.^{189,198}

Furthermore, (111) surfaces are theoretically predicted to have up to $\chi = 2.63$ eV,¹⁹⁸ while fluorinated (113) interfaces are estimated to yield *ca.* $\chi = 3.30$ eV.²¹⁵ In addition, recent density functional theory calculations suggest that this termination is also highly suitable for the less-studied (110) interface.^{198,258}

Experimentally, fluorine termination has been achieved using several techniques. Rietwyk *et al.* utilized exposure to dissociated XeF₂, measuring a PEA of $\chi = 2.56$ eV for a (100) surface.²⁰⁴ In addition, Cui and Hu tested the influence of fluorine-terminated (100) diamond, prepared using a CF₄ plasma (Fig. 5).²⁵⁹ Analysis with X-ray photoelectron spectroscopy revealed that a 5-minute exposure led to a *ca.* 3 nm-thick polymerized fluorocarbon on the surface. Moreover, charge-state-dependent NV fluorescence measurements revealed a higher ζ for fluorine-terminated diamond than for oxygen

and hydrogen termination. Similar results were obtained for nanodiamonds treated with electron-beam-induced fluorination, which allows for highly localized surface modification.²⁶⁰ Finally, Osterkamp *et al.* demonstrated the stabilization of shallow NVs using SF₆ plasma exposure, enabling NMR signal detection from protons in immersion oil on the diamond surface.¹⁴⁷

In contrast to these results, Ohashi *et al.* found that a brief (15 s) treatment with CF₄ plasma led to permanent bleaching of *ca.* 30% of shallow NV centers.²²⁰ This experiment underlines the critical importance of reducing acceptor states and charge traps at the diamond surface, even for interfaces with large global PEA.

3.3.2 Oxygen surface termination. Oxygen-terminated surfaces offer a highly promising route to stabilize shallow NV centers while allowing for subsequent chemical functionalization. Importantly, we note that coverage by different oxygen-containing functional groups, such as hydroxyl (C–OH), carboxylic acid (COOH), carbonyl (C=O), and ether (C–O–C) groups, impact both χ and as the presence of deleterious sub-bandgap surface states. Such states may perturb the excited-state energy levels of nearby NV centers, impacting their charge stability.¹⁸⁹ In addition, we note that different diamond surface planes may also strongly impact χ and the presence of surface states. Indeed, recent theoretical work by Li *et al.* suggests that the oxygenated (113) diamond surfaces may increase optical stability of near-surface NV centers compared to the commonly used (100)- and (111)-cut diamonds.²¹⁵

Full termination with hydroxyl groups is theoretically predicted to yield NEA of $\chi = -0.6$ eV and PEA of $\chi = 0.2$ eV for (100) and (111) diamond surfaces, respectively,²⁴⁷ and may yield sub-bandgap states in the case of (100) surfaces.¹⁸⁹ Similarly, carboxyl groups can introduce deep, localized acceptor states that quench NV luminescence.¹⁸⁹ Moreover, ether-like bridges on oxidized (100) surfaces were theoretically calculated to induce a PEA of $\chi = 2.4$ – 2.63 eV;^{189,198,199} however, photo-excited electrons from NV[−] may be trapped by such surfaces, resulting in blinking.¹⁸⁹ Encouragingly, epoxy-oxidized (111) surfaces were recently predicted to have PEA of $\chi = 1.85$ eV without generation of sub-bandgap states.²¹⁰ Moving forward, it is likely that a combination of these terminators will be required to yield both optimal PEA and reduced surface states.^{189,261}

In practice, oxygen termination results from the use of strongly oxidizing acids (*e.g.*, piranha solution and “tri-acid” mixtures of 1 : 1 : 1 H₂SO₄ : HClO₄ : HNO₃),^{21,22,221,226,262,263} oxygen plasma,^{196,264–266} thermal annealing in an oxygen atmosphere,^{30,265,267} UV/ozone,²⁶⁸ or ozone treatments.²⁶⁹ Importantly, such treatments often result in a surface that is decorated by a mixture of oxygen containing functional groups. Various surface characterization methods can be used to distinguish between these terminal groups and to measure their influence on the surface electronic structure²⁷⁰ including X-ray photoelectron spectroscopy (XPS), ultraviolet photoelectron spectroscopy (UPS), near-edge X-ray absorption fine-structure (NEXAFS) spectroscopy, high-resolution electron-loss

spectroscopy (HREELS), and Fourier-transform infrared (FTIR) spectroscopy. However, deterministic control over the relative ratio of these groups is not trivial, and different oxidation procedures yield variable compositions.²⁷¹ Moreover, surface roughness and crystallographic orientation also influence the coverage.^{272,273} Finally, depending on how harsh the oxidation process is, some procedures may result in undesired graphitization.

Experimentally, surface oxidation treatments have consistently shown improvements in T_2 times for near-surface NVs, as well as higher ζ both for bulk^{196,265} and nanodiamond materials.^{49,274} Fu *et al.* showed efficient conversion of NV⁰ to NV⁻ for *ca.* 10–75 nm-deep emitters after annealing at 465 °C in an oxygen atmosphere (Fig. 6a).¹⁹³ Moreover, Fávoro de Oliveira *et al.* observed a threefold increase in T_2 following an O₂ soft plasma exposure compared to tri-acid-cleaned surfaces (Fig. 6b).²⁶⁴ In addition, Yamano *et al.* demonstrated an improvement in Rabi oscillation contrast; the $C = 0.14$ observed for shallow NV centers in acid-cleaned diamond increased to $C = 0.30$ after UV/ozone treatment, further improving to $C = 0.43$ following oxygen thermal annealing (Fig. 6c).²⁶⁷ More recently, Sangtawesin *et al.* reported on the impact of thermal oxygen annealing on shallow NV-center spin coherence, along with complementary characterization of the surface morphology (Fig. 6d–f).³⁰ They reported an up to a factor-of-four improvement in T_2 for shallow NV centers compared to samples prepared with tri-acid cleaning alone. These improved properties were attributed to the formation of a highly ordered, predominantly ether-terminated surface. This ordering was facilitated by fabrication of extremely flat (100) surfaces with rms roughness of <0.4 nm. In contrast, Braunbeck *et al.* studied the impact of mechanical polishing and etching techniques on coherence times for shallow emitters and found minimal correlation with surface roughness.²⁷⁵ These findings suggest that the particular method of preparing flat diamond surfaces (*i.e.*, etching, polishing, *etc.*) likely has a strong influence on the chemical termination.

In some cases, surface oxidation can have minimal impact on T_2 while having a significant influence on T_1 for shallow emitters. For example, Ohashi *et al.* observed no significant change in T_2 after oxidation (compared to H-terminated surfaces after tri-acid cleaning) but observed a larger spread in relaxation times ($T_1 \approx 0.54$ –4.2 ms after compared to $T_1 \approx 2.7$ –3.8 ms before oxidation).²²⁰ Moreover, Tétienne *et al.* saw that thermal annealing in oxygen for 4 h at 465 °C had little influence on T_2 and no effect on the average photoluminescence rate or Rabi contrast.²⁷⁶ In contrast, such annealing resulted in a two-order-of-magnitude reduction in T_1 for some emitters; however, longer T_1 times could be recovered after tri-acid cleaning. In summary, the experimental results reported for oxygenated diamond surfaces underline the complexity of the relevant spin and charge dynamics that impact shallow NV centers.

3.3.3 Nitrogen surface termination. Nitrogen-terminated surfaces have recently received increased attention as an alternative to the more widely employed oxygen treatments.

Crucially, the band bending (and resulting electron affinity) at the surface depends sensitively on the bonding nature of the nitrogen atoms.^{277–279} In addition, termination with nitrogen has additional side benefits, including reduced electron-spin noise as well as the potential to create well-defined arrays of nitrogen nuclear spins ($I = 1$ or $I = 1/2$ for ¹⁴N and ¹⁵N, respectively) that can be probed with NVs.²¹¹

Theoretical results from Stacey *et al.* showed that (2×1)-reconstructed (100) surfaces that are fully terminated with nitrogen exhibit a PEA of $\chi = 3.46$ eV, while (2×2)-reconstructed surfaces with 50/50 N/H termination exhibit a PEA of only $\chi = 0.32$ eV (Fig. 7a).²⁰³ Furthermore, Chou *et al.* performed first-principles calculations of (111) diamond surfaces in which terminal carbon atoms could bind to a single hydrogen. With this model, they found that an over 50% substitution of C–H units by isovalent nitrogen led to PEA (Fig. 7b and c),²¹¹ with full nitrogen coverage resulting in $\chi = 3.23$ eV. Interestingly, unlike the (100) and (111) surfaces, nitrogen termination of (113) diamond was proposed as unsuitable for NV sensing since surface-state mixing with the NV excited state would lead to photoionization.²¹⁵

Experimentally, nitrogenation of diamond surfaces has been achieved using anodic polarization in liquid ammonia (requiring conductive, *e.g.*, boron-doped diamond),²⁸¹ plasma treatment with nitrogen (N₂),^{203,282–285} ammonia (NH₃),^{286–289} or mixed sources,²⁸¹ radical beam exposure,²⁸⁰ and UV irradiation in NH₃ gas.²⁹⁰ In these experiments, photoelectron spectroscopies including XPS, NEXAFS, and HREELS were used to probe the binding configuration of nitrogen atoms. The resulting nitrogen may be incorporated as nitrile (CN) groups, imines (C=N), single-bonded (C–N, N–N), or amine (NH_x) species.

In a recent study, Kawai *et al.* demonstrated the stabilization of the NV⁻ charge state in shallow defects using nitrogen radical beam exposure (Fig. 7d).²⁸⁰ This method is suspected to produce diamond surfaces with a mixture of nitrogen terminations, as characterized by XPS and NEXAFS. Using this technique, the authors reported increased Rabi oscillation contrast compared to NV centers in oxygen-terminated diamond (prepared by hot acid treatment and VUV/ozone exposure). Furthermore, measured T_2 values were comparable to prior reports on oxygen-terminated surfaces.²⁹¹ Subsequently, 4–10 nm-deep emitters were used for NV-NMR detection of ¹H spins in immersion oil.

Interestingly, nitrogenation can also impact the fractional coverage of sp² and sp³ carbon, a phenomenon that is heavily dependent on the process parameters and diamond surface morphology. For example, a radio-frequency plasma based on a mixture of NH₃/N₂ diluted in H₂ was shown to induce surface graphitization on polycrystalline, boron-doped diamond.²⁸¹ In contrast, we recently showed that exposure of oxygen-terminated, single-crystalline (100) diamond surfaces to NH₃ plasma resulted in a reduction of residual sp² carbon, which may be linked to an observed increase in T_2 for shallow NV centers.²⁸⁹

Moving forward, derivatization (*e.g.*, of amines) enables complementary tests of chemical functionality. While the

introduction of reactive amine functional groups enables facile attachment of molecules, fully amine-terminated diamond surfaces were experimentally shown to exhibit NEA,²⁸⁸ and are thus incompatible with near-surface NV centers. Therefore, mixed surface terminations are likely preferable to maintain NV stability while allowing for covalent molecular attachment.^{203,289}

4 Surface functionalization for molecular sensing with NV centers

NV-center detection of external molecular targets requires both molecular immobilization on the diamond surface and preservation of emitter properties *via* the aforementioned techniques. While the detection of magnetic noise arising from electron^{292,293} and nuclear spins^{21,22,27–29,147,280,294} external to the diamond has been demonstrated, robust and deterministic functionalization of the diamond surface will prove critical for future experiments. Indeed, such functionalization could facilitate observation of, *e.g.*, surface reactions, conformational changes in biomolecules, spin-dependent effects in charge transfer, and target binding to receptors (such as antibodies or aptamers). Moreover, directed and self-assembly of molecules on surfaces provides well-defined specificity and selectivity, as well as control over molecular orientation (*e.g.*, the availability of binding sites or functional groups) and density, further motivating its development.

Despite being widely regarded as chemically inert, numerous techniques exist to functionalize diamond surfaces, which are the focus of recent reviews.^{271,295} However, not all strategies for molecular attachment to diamond are compatible with high-quality, shallow NV centers; for example, electrochemical methods, such as diazonium grafting,^{296,297} require conductive (*e.g.*, boron-doped) diamond. These substrates are typically incompatible with NV sensing experiments, which require ultra-high-purity substrates. In addition, while direct modification of hydrogen-terminated diamond is possible,^{298–302} it is not be suitable for charge stabilization of near-surface NV[−] since local band bending promotes the neutral charge state.¹⁹⁶ In this section, we explore strategies for stable non-covalent and covalent grafting of molecules to diamond that are compatible with near-surface NV centers. In particular, we focus on covalent attachment for oxygen- and nitrogen-terminated surfaces, in addition to molecular self-assembly on oxide adhesion layers that are grown on diamond.

4.1 Noncovalent functionalization

One functionalization approach employs non-covalent attachment by physisorption, which is stabilized by, *e.g.*, hydrogen-bond interactions or electrostatic attraction. Alternatively, large molecules of interest (*e.g.*, proteins) could be immobilized within solid polymer matrices that restrict translational and rotational degrees of freedom. Indeed, such a route may prove useful for NV-NMR-based approaches for elucidation of structural information. Moreover, solid supports could take

advantage of dielectric shielding to mitigate the impact of electronic noise on NV-center sensors.

For example, Shi *et al.* used a polylysine matrix to immobilize mitotic arrest deficient-2 (MAD2) proteins that were modified with nitroxide spin labels.²³ These molecules were drop-cast onto the diamond surface before freeze drying with liquid nitrogen (Fig. 8a and b).²³ Shallow NV centers were subsequently used to monitor dilute densities of these proteins using EPR measurements. Notably, even though motion was restricted by the polylysine matrix, protein dynamics persisted on the millisecond time scale, resulting in spectral broadening of the EPR spectra. Consequently, improved surface functionalization and NV sensing schemes are required for detection of hierarchical ordering and conformational changes in biomolecules.

Interestingly, Kayci *et al.* recently developed a sandwich bioassay that bypasses diamond functionalization in favor of modifying glass substrates with indexed droplets of hydrogel microstructures.³⁰³ These substrates are then brought into close proximity to a diamond containing near-surface NV centers for sensing (Fig. 8c–e).³⁰³ This approach relied on magnetic-nanoparticle-tagged DNA for nucleic acid detection; briefly, poly(ethylene glycol)diacrylate-based hydrogel microstructure networks were polymerized with acrylamide-functionalized oligonucleotides. Complementary target DNA (conjugated with magnetic nanoparticles) then hybridized with probe sequences, resulting in a modified NV ODMR signal. Three-dimensional hydrogel structures hosting bioreceptors could also be patterned directly on planar diamond substrates for applications necessitating direct diamond surface modification.

Overall, non-covalent functionalization is attractive due to the ease of achieving physisorption compared to chemisorption, particularly for diamond substrates where the density of functional groups may be limited. Nevertheless, under normal sensing conditions, desorption of physisorbed molecules occurs more readily than for covalently tethered species. Furthermore, non-specific binding may pose a significant issue when relying on non-covalent attachment methods alone.³⁰⁴

4.2 Covalent functionalization

In contrast to non-covalent techniques, chemisorption offers greater stability and control over molecular attachment to surfaces that exhibit well-defined chemical terminations. In practice, the optimal chemical modification procedure and starting diamond surface termination are dependent on the available functional groups of the target molecule. Fig. 9 highlights some selected pathways to functionalize oxygen- and nitrogen-terminated diamond surfaces, which are of great interest due to their compatibility with near-surface NV centers for sensing applications (see Section 3).

4.2.1 Functionalizing oxygen-terminated diamond. Conveniently, residual carboxylic acid groups resulting from surface oxidation may be functionalized directly.^{273,305} However, the fraction of native carboxylic acid groups is typically low,³⁰⁶ resulting in dilute attachment that is most suitable for single-to few-molecule experiments.

Fig. 8 NV studies with non-covalently modified surfaces. (a) Schematic of proteins labeled with nitroxide spins and dispersed within a polylysine matrix layer on a diamond surface. (b) EPR spectrum characteristic of the nitroxide spin label tethered to proteins under study. Signals disappear after removal of the proteins from the surface. For example, Sushkov *et al.* employed a 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC)/*N*-hydroxysuccinimide (NHS) crosslinking chemistry to tether paramagnetic molecules composed of a gadolinium ion (Gd^{3+}) chelated by an amine-terminated ligand to carboxylic-acid moieties on diamond (Fig. 10a and b).²⁶ Co-localization of isolated molecules using single NV centers allowed for detection of an individual $S = 7/2$ electron spin from a (Gd^{3+}) chelated molecule using T_1 relaxometry. Lovchinsky *et al.* later used the same crosslinking chemistry to immobilize ubiquitin proteins *via* exposed

carboxylic acid groups on the protein (Fig. 10c and d).²⁴ This dilute attachment, in combination with enrichment of the protein with 2H and ^{13}C , allowed the authors to detect proteins on the surface using single, shallow NV centers. Moving forward, more precise control over specific binding to orient proteins (*e.g.*, antibodies), such as labeling with His-tags, or targeting thiolated cysteine residues, will prove highly useful. In particular, specific binding will enable subsequent target attachment to immobilized receptors, as well as positioning of active sites in close proximity to the surface.

Fig. 9 Schematic depiction of common functional groups at the surface of oxygen- and nitrogen-terminated diamond, and selected pathways for covalent functionalization as described in the main text.

Oligonucleotide probes may also be tethered using readily available modifications to the ends of the sugar phosphate backbone. For example, Shi *et al.* functionalized carboxylic acid groups on diamond nanopillars hosting single NV centers with NH_2 -modified probe sequences. They subsequently detected hybridization with nitroxide-labeled complementary strands using EPR measurements (Fig. 10e and f).²⁵

Finally, hydroxyl groups can be used to attach molecules of interest by esterification^{307–310} and thermal alkylation.³¹¹ Moreover, hydroxyl groups may serve as anchoring points for phosphonic acid headgroups,³¹² for silanization,^{313–315} or for precursor molecules in growth of capping films *via* atomic layer deposition (see Section 4.2.3). Starting with oxygen-annealed diamond substrates, Grotz *et al.* used silanization to covalently bind the 4-maleimido-TEMPO spin label.³¹⁶ The authors employed DEER techniques to monitor Rabi nutations of surface-bound electron spins and measured the coupling strength between spin labels and NV-center probes. In addition, we demonstrated surface NMR detection using vapor-deposited trimethoxy(3,3,3-trifluoropropyl)silane, as well as (3-amino-propyl)trimethoxysilane, that were subsequently exposed to trifluoromethyl tags for amine-reactive crosslinking.²⁸⁹ In this work, signals from ^{19}F spins were readily detected *via* NV NMR, however, multilayer film formation could not be ruled out. Generally, preventing multilayer formation or silane film degradation under aqueous conditions or air exposure is difficult and the mechanism for molecular assembly on oxidized surfaces is not fully understood. Still, silanization provides a facile route toward dense surface functionalization.

4.2.2 Functionalizing nitrogen-terminated diamond.

Nitrogen-terminated diamond surfaces decorated with amine groups can be used to anchor molecules in a variety of ways. Analogous to crosslinking of molecules hosting amine groups to carboxylic acid moieties on oxygen-terminated diamond, amide bond formation *via* EDC/NHS coupling chemistry can also be used in the reverse way for amine-terminated substrates.^{305,317} Bifunctional linkers lead to exposed COOH groups on initially amine-terminated surfaces for subsequent EDC/NHS reactions.³¹⁸ Amine-to-sulfhydryl crosslinking with

m-maleimidobenzoyl-*N*-hydroxysuccinimide ester may also be used for directed attachment, *e.g.*, of thiolated oligonucleotide probes or proteins containing cysteine residues. Aminolysis with 4-pentynoic acid in the presence of *N,N'*-dicyclohexylcarbodiimide (DCC) and 4-(dimethylamino)-pyridine (DMAP) was shown to enable catalyst-free thiol-yne coupling on diamond.³¹⁹ Amine-functionalized molecules may also be crosslinked to amines on the diamond surface using glutaraldehyde.²⁹⁰

Recently, we introduced a strategy for direct chemical functionalization of terminal amine groups using mixed nitrogen- and oxygen-terminated (N/O) surfaces prepared using NH_3 plasma following a thermal oxygen anneal.²⁸⁹ Importantly, short plasma exposure times (*ca.* 20 s) resulted in increased coherence times for NV centers <10 nm from the surface and significantly reduced background fluorescence from the diamond interface. Subsequent chemical functionalization of the mixed N/O-terminated diamond surfaces *via* highly generalizable amine-reactive crosslinking allowed for tunable molecular density and recyclable functionalization. Finally, NV-NMR measurements were used to detect surface-bound analytes with trifluoromethyl tags in the few-molecule (<200 molecules) regime. While promising, this approach is hampered by a decrease in the number of NV centers that exhibited ODMR signal for long NH_3 plasma exposure times. The mechanism of this destabilization is not well understood, but may be linked to a concomitant increase of reactive amine groups that can contribute to NEA surfaces.²⁸⁸ Moving forward, situations requiring a high surface density of analytes crosslinked to surface-bound amine groups may benefit from co-doping with electron donors to aid in stabilizing the NV^- state.¹⁴²

4.2.3 Atomic layer deposition of oxide adhesion films. An alternative to directly binding molecules on the diamond surface employs an intermediate amorphous oxide capping layer that enables straightforward chemical functionalization.³²⁰ Specifically, atomic layer deposition (ALD) can be used to deposit adhesion films for subsequent molecular attachment *via* well-established oxide chemistries, *e.g.*, with phosphonate or silane headgroups. Recently, Liu *et al.* used ALD to grow *ca.* 1 nm-thick capping layers of Al_2O_3 on diamond substrates before

molecular assembly using phosphonate anchoring groups (Fig. 11).³²¹ Introduction of the ALD layer was found to slightly reduce T_1 and T_2 times for NV centers located *ca.* 5–12 nm below the surface; however, the resulting sensitivity was sufficient to perform ensemble NV-NMR measurements of ¹⁹F and ¹H in molecules during the formation of a self-assembled monolayer. Such real-time observation of molecular signals

highlights the exciting potential for NV-NMR spectroscopy to track a wide range of surface chemical reactions over the timescales of minutes to hours.

Similarly, Xie *et al.* used *ca.* 2-nm-thick ALD-grown Al₂O₃ adhesion layers on oxygen-terminated diamond to test surface functionalization, chemical stability, and preservation of shallow NV sensors (Fig. 12).³²² Subsequent silanization of these layers

enabled grafting of polyethylene glycol (PEG) moieties and attachment of proteins and DNA molecules. Functionalization with PEG molecules is promising as it yields highly biocompatible surfaces and minimizes non-specific binding.^{304,323} While ALD and functionalization resulted in decreased coherence times for shallow (2.3–11 nm deep) NV centers compared to pristine diamond surfaces, some NVs still exhibited coherence times of up to 100 μs, which are sufficiently long for quantum sensing experiments. Moreover, the authors showed that the Al₂O₃ layer can be removed by KOH, providing an easily recyclable NV-sensing platform.

In summary, these recent examples show the benefit of amorphous oxide capping layers for NV-center sensing of functionalized diamond surfaces. Specifically, ALD affords precise control of adhesion layer thickness, enables the formation of dense monolayer coverage of molecular adsorbates, and facilitates recyclable surfaces through removal and regrowth. Nevertheless,

there are challenges that accompany this functionalization strategy; the adhesion layer leads to increased distance between the NV and target spin, resulting in decreased signal (see Section 2.3). Moreover, the spin and charge properties of shallow NV centers were observed to degrade with application of ALD layers. Indeed, depending on the stoichiometry of aluminum and oxygen in Al_xO_y films, the layers can induce unfavorable electron affinity.³²⁴ In addition, these films may also host paramagnetic defects leading to reduced T_2 times.^{325,326}

5 Measurement strategies to mitigate surface noise

In addition to the aforementioned materials optimization and surface chemistries, several strategies can be employed during measurement to mitigate the effects of noise on the NV center.

Typically, such measurement sequences increase the sensor coherence time or realize a detection method that is immune to certain noise sources. While a complete overview of the methods for reducing the effects of noise *via* careful engineering of the measurement protocol (or measurement “hardening”) is beyond the scope of this work, we point the reader towards dedicated review articles.^{10,43} In the following section, we discuss illustrative examples for combating unwanted surface effects through experimental sequences. Importantly, the improvements in sensitivity afforded by such techniques are complementary to the advanced surface chemistry discussed thus far.

5.1 Dynamical decoupling

While dynamical decoupling (DD) sequences were not initially developed for sensing, they have proven exceptionally useful for detecting signals at the specific frequencies where they do not refocus the signal,^{10,78,221,327} a phenomenon known as “recoupling”.

The simplest DD sequence is the Hahn-echo protocol,⁷⁰ comprising a single π pulse that protects the NV center from dephasing caused by variations in the magnetic field that are slow compared to the experiment duration. The basic idea is illustrated in Fig. 3: any phase accumulation on the NV center caused by variations in B_0 are refocused. Similarly, decoherence from magnetic-field fluctuations at higher frequencies can be mitigated by instead applying a train of π pulses, with the interpulse delay τ dictating the high-frequency cut off ($1/\tau$) of the noise spectrum. In such cases, the magnetic field must

remain constant over shorter interpulse delays to achieve a refocusing. As a result, dynamical decoupling protocols can substantially enhance observed coherence times; in contrast, the magnetic noise at $f = 1/(2\tau)$ is instead integrated.

This phenomenon can be exploited for sensing environmental noise *via* changes in coherence at specific frequencies, essentially using the NV as a magnetic spectrum analyzer. Such sequences have also been used in scanning probe experiments to detect signals originating from AC-modulated single spins,³²⁸ currents,³²⁹ magnetic gradients^{330,331} and electric fields.⁸⁴ For noise with frequency f , refocusing will occur for sequences with $\tau = 1/(2f)$ as well as for harmonics $\tau' = N/(2f)$, where $N = 2n + 1$. Moreover, DD sequences may exhibit spurious sub-harmonics for finite-width pulses dependent on the phase cycling.⁵⁷

Sequences containing over 10^4 π pulses have been successfully applied to a target NV center,^{55,332} resulting in coherence times exceeding one second at cryogenic temperatures.⁵⁵ It is therefore of crucial importance that DD sequences do not themselves introduce significant errors, necessitating either high-fidelity pulses⁴⁶ or fault-tolerant sequences. For example, a significant reduction in error can be achieved using a scheme proposed by Meiboom and Gill,³³³ who adapted the Carr-Purcell (CP) sequence

$$\left(\frac{\pi}{2}\right)_x (-\tau/2 - \pi_x - \tau/2)^n \left(\frac{\pi}{2}\right)_\theta \quad (21)$$

into a sequence that is now referred to as “CPMG”

$$\left(\frac{\pi}{2}\right)_x (-\tau/2 - \pi_y - \tau/2)^n \left(\frac{\pi}{2}\right)_\theta, \quad (22)$$

which provides first-order correction for amplitude, frequency, and timing errors. The phase θ of the last $\pi/2$ pulse can be tuned to select different sensing schemes¹⁰ and can prevent the accumulation of pulse errors under realistic experimental conditions. Further error correcting protocols of note include the XYXY sequence, the popular XY-N protocols,³³⁴ and the Knill dynamical decoupling protocol (KDD).³³⁵

Such sequences have proven exceptionally useful for detecting, and even controlling, proximal nuclear spins. As with any other source of magnetic noise, DD sequences can very efficiently decouple the NV center from a bath of proximal spins if they are not also refocused by the DD pulses,⁵⁵ which is typically the case due to the large zero-field splitting of the NV center. Additionally, DD protocols can impart back-action on coupled nuclear spins, which can be used as a resource for realizing coherent control over a multi-spin system.^{336,337} Encouragingly, recent efforts have made progress in designing DD sequences that refocus noise at only one frequency, suppressing spurious harmonics at the expense of a reduction in signal.^{338,339}

5.2 Coherent driving of surface spins

Dynamical decoupling alone cannot mitigate noise from residual paramagnetic impurities (*e.g.*, electron spins associated with dangling bonds at the surface or substitutional nitrogen centers) due to their fast Larmor precession at typical magnetic

bias fields. However, if such spins have sufficiently long T_1 times, one can combat noise by employing continuous, coherent driving of the spin bath.^{340,341} This complementary approach aims at engineering the spectral density of the magnetic noise generated by the electron spin bath itself. In practice, the bath spins are driven with Rabi frequency Ω , which leads to periodic modulation in the resulting noise at the NV location. Essentially, such driving shifts the center of the magnetic noise spectrum from $f = 0$ to $f = \Omega$, which can reduce the spectral overlap with the NV measurement window,¹⁰ resulting in an increased NV coherence time. Noise can be reduced further by spectral engineering of the applied field³⁴² or by using pulsed schemes.^{340,343}

Previously, such techniques have been used to reduce dephasing for NV-rich diamonds with large nitrogen content. However, coherent driving of the spin bath is applicable to any paramagnetic spins that exhibit sufficiently long T_1 times, including nuclear spins. However, in this case, low nuclear gyromagnetic ratios pose a challenge in achieving high driving frequencies but also reduce the magnetic noise generated by such species.

5.3 Repetitive measurement and readout schemes

Often the sensor coherence time is insufficient for achieving the desired spectral resolution using standard DD protocols; in such cases, weak-measurement techniques may serve as a viable alternative.^{61,62} Such measurement schemes are appropriate only when coherent detection is possible (*e.g.*, measuring coherently coupled nuclear spins) and involve applying sequential, weak measurements that result in limited back-action on the target spin. Since the NV center can be reinitialized between sequential measurements, the spectral resolution is no longer limited by the NV T_2 time and instead by that of the target nuclear spin. Importantly, we note that the measurement sensitivity is still limited by the NV T_2 , motivating the use of highly coherent emitters.

5.4 Double-quantum sensing

Most measurement protocols leverage only two of the three spin states within the ground-state manifold ($|m_s = 0\rangle$ and $|m_s = \pm 1\rangle$, see Section 2). In contrast, double-quantum protocols make use of the full spin-triplet subspace to obtain higher sensitivity. For example, in the Ramsey-like experiment shown in Fig. 3a, the first $(\pi/2)$ pulse would be replaced by two pulses: a $(\pi/2)_y$ pulse on the $|0\rangle \leftrightarrow |-1\rangle$ transition followed by a $(-\pi)_y$ pulse on the $|0\rangle \leftrightarrow |+1\rangle$ transition. These rotations result in an equal superposition of both the $|-1\rangle$ and $|+1\rangle$ states

$$|\psi\rangle = \frac{1}{\sqrt{2}}(|-1\rangle + |+1\rangle). \quad (23)$$

During the measurement evolution period, phases are imprinted on both basis states with opposite sign

$$|\psi\rangle = \frac{1}{\sqrt{2}}\left(e^{-i\gamma_{\text{NV}}\int B(t)dt}|-1\rangle + e^{i\gamma_{\text{NV}}\int B(t)dt}|+1\rangle\right). \quad (24)$$

Finally, this state is mapped back to the starting basis through application of the same pulses in reverse order. The resulting

measurement yields double the signal when compared to the single-quantum approaches described in Section 2. An additional benefit of double-quantum techniques are their immunity to common-mode shifts that affect both sub-levels in the same manner. For example, variations of the zero-field-splitting constant caused by temperature shifts,⁸⁹ axial electric or strain fields³⁴³, and transverse magnetic-field fluctuations.³⁴³ If such noise sources dominate the coherence loss, double-quantum DD may yield longer coherence times than single-quantum approaches. However, for longitudinal magnetic fluctuations, the doubled phase accumulation often comes at the cost of a $\sim 2 \times$ reduction in T_2 .^{344,345}

6 Emerging applications

The previously surveyed methods for diamond-surface functionalization could be used in concert with the exceptional sensitivity and spatial resolution of the NV to provide new approaches for molecular-level detection. Indeed, NV sensors could revolutionize many active areas of research since they operate at ambient conditions with minimal perturbation to the system of interest.³⁴⁶ In the following section, we highlight a selection of emerging applications within various fields of chemistry and biology that would benefit from (or necessitate) covalent attachment to a well-defined, functionalized diamond surface (summarized in Fig. 13), underscoring the immense potential of the NV-center sensing platform.

6.1 Structure–function relationships in biomolecules

The potential for NV sensors to elucidate the structure of small to hierarchically more complex biomolecules (*e.g.*, proteins) has been widely posited.^{17,23,24,347} While the first demonstration of NV-center NMR of external nuclear spins in chemical samples dates back to 2013,^{21,22} three-dimensional mapping of such spins within a molecule remains an outstanding challenge.

Conventional solid-state NMR has made tremendous progress in structural analysis by employing fast magic-angle spinning (MAS)³⁴⁸ and high magnetic fields³⁴⁹ to achieve the exquisite spectral resolution required for detecting small chemical shifts. In contrast, NV center experiments are typically carried out at low applied magnetic field and MAS cannot (yet) be applied, precluding such detection. Nevertheless, NV centers could still be used to measure structure-function relationships in biomolecules *via* position-dependent hyperfine interactions with nuclear spins rather than chemical-shift differences.^{350,351} Furthermore, changes in the magnitude of magnetic noise detected from the Larmor precession of nuclear spin labels can serve as a proxy for conformational changes (*e.g.*, opening of DNA hairpins).

Finally, optical pumping of the NV-center spin can provide a local, low-entropy source of nuclear-spin polarization that could provide complementary structural information to conventional NMR and EPR techniques. In such experiments, nuclear spins coupled to the NV center are polarized beyond the thermal limit by transferring polarization from the NV.^{352–355}

Fig. 13 Schematic overview of emerging applications for shallow NV centers that are discussed in Section 6. Applications highlighted in this Review make use of diamond with well-defined surface termination (i.e., controllable density of anchoring sites and layer thickness as well as conserved NV properties) to which molecules of interest are covalently attached.

Subsequently, the polarized spin bath can be detected classically (using NMR pick-up coils) or coherently using the NV center.⁶¹

6.2 Biosensing

The biocompatibility of diamond supports the use of NV centers for bio-sensing applications.^{356,357} To that end, the *in vitro* detection of viral RNA using NV centers was first demonstrated in 2020 using a lateral-flow format for HIV diagnosis.³⁵⁸ In this work, the presence of HIV-1-RNA caused immobilization of antibody functionalized nanodiamonds, which was subsequently observed *via* NV fluorescence readout. In addition, Li *et al.* proposed a sensing scheme for SARS-CoV-2 RNA that exploits T_1 relaxation of NV centers in nanodiamonds.³⁵⁹ In analogy to earlier work on pH and redox sensing,³⁶⁰ they propose Gd³⁺ as a source for magnetic noise. Specifically, nanodiamonds could be coated with DNA strands containing electrostatically bound Gd³⁺; upon base-pair matching with the complementary viral RNA, the DNA molecules including Gd³⁺ complexes would be released from the diamond surface. This reaction would result in decreased noise and therefore longer relaxation times for near-surface NV centers.

Notably, the majority of NV biosensing research has thus far leveraged nanodiamonds rather than bulk substrates, which can directly utilize many of the diamond surface preparation and functionalization strategies described in this Review. Further supported by significant advancements in production and purification of nanodiamonds, this alternate platform has seen application in biomedical sensing and imaging,^{361–365}

drug delivery,³⁶⁶ and reaction monitoring,^{233,367} as discussed in recent reviews.^{346,368,369} Specifically, these experiments have monitored physiological variables, such as concentration of ions, radicals, and biomolecules, in addition to pH, temperature, and redox potential or forces.³⁵⁷ Informed by these efforts, bulk diamond substrates offer a complementary or alternative sensing platform for hosting NV centers with significantly improved spin properties. It is worth noting that motivations for chemical control of bulk surfaces may differ from those of nanodiamonds intended for studies of aggregation, protein corona formation, cellular uptake, and targeted delivery. In addition, alignment of the magnetic field required for NV-center experiments is simpler for bulk substrates than for randomly orientated nanocrystals.^{370,371} Nevertheless, both nano- and bulk-diamond platforms would benefit from improved NV-center properties and deterministic surface functionalization protocols, motivating progress in this field.

6.3 The radical-pair reaction

Radical pairs are reaction intermediates that either encounter each other in solution or are created simultaneously, usually by a chemical reaction such as homolytic bond cleavage or photo-induced electron transfer (e.g., in blue-light photoreceptive cryptochromes).^{372–374}

Research on radical pairs began in the late 20th century in the context of Chemically Induced Dynamic Nuclear Polarization (CIDNP)³⁷⁵ and Chemically Induced Dynamic Electron Polarization (CIDEP). Later, this research gained interest in

the area of magnetic-field effects (MFE),^{376–378} including low-field effects with biological significance^{379,380} (e.g., magnetoreception in birds^{381,382}). Currently, most radical-pair research focuses on spin-correlated states, which may be either a spin singlet or triplet state.³⁸³ Since radical recombination commonly occurs solely from the singlet state, the inter-conversion between singlet and triplet states, which is mainly driven by differences in Zeeman frequencies and hyperfine interactions with surrounding nuclei, is a crucial parameter for the chemical outcome.

Recently, Finkler *et al.* proposed to use the NV as a sensor for observing this radical-pair mechanism.³⁸⁴ In such an experiment, a nearby radical pair would experience an effective magnetic field (and therefore singlet-to-triplet conversion rate) that depends on the spin state of the NV sensor. An alternate strategy was introduced by Liu *et al.*³⁸⁵, who proposed to use the electric-field sensitivity of the NV to measure radical-pair recombination rates. Essentially, the charge-separated state of the pair generates a non-zero electric field at the NV position that vanishes upon recombination. Consequently, detection of this field would enable measurement of recombination rates at the single-molecule level. We note that both proposals rely on radical-pair generation in proximal molecules, which would benefit greatly from the advances in diamond functionalization discussed in this Review.

6.4 Chiral-induced spin selectivity

Chiral-induced spin selectivity (CISS) refers to enantioselective and electron spin-dependent transmission of electrons through chiral molecules and crystalline materials.^{386,387} While spin-selective electron transfer is typically associated with magnetic materials or those possessing substantial spin-orbit coupling, the discovery of the CISS effect suggests that organic molecules lacking inversion symmetry that are composed of low-atomic-weight building blocks may also be promising systems for spintronics applications.³⁸⁸ Since this discovery, experiments have revealed large asymmetry in the scattering probability of polarized photoelectrons traversing thin organized films of chiral organic molecules,^{388–392} observed spin selectivity in the conduction regime,^{393–396} and measured spin-dependent charge polarization within molecules and at surfaces.^{397–399} However, despite concurrent advances in theoretical models to describe this effect,^{400–406} questions remain regarding the role of spin coherence and the magnitude of spin polarization accompanying electron transport within chiral molecules. Moreover, the majority of CISS measurements have relied on ferromagnetic electrodes, which may perturb observed polarizations due to the interface between ferromagnetic surfaces and the chiral material.^{407–410}

Several recent proposals outline methods for studying CISS *via* magnetic-resonance experiments.^{411–413} Chiesa *et al.* described methods for detection through either asymmetry in the dipolar coupling between the sensor and the polarized spin or *via* polarization transfer from the polarized spin to the sensor.⁴¹¹ Meanwhile, Fay *et al.* suggested monitoring coherence associated with CISS in the presence of a magnetic field

that is orthogonal to the chiral axis.⁴¹² Critically, proposed experiments necessitate well-aligned molecular assemblies. Moreover, application of conventional NMR and EPR measurements may be limited by the need for substantial magnetic fields and large spin ensembles. In contrast, NV centers present a promising method for detection of CISS locally at the nano-scale. Notably, NVs were used to indirectly probe CISS by Merzeida *et al.*,⁴¹⁴ who measured the magnetization orientation in a ferromagnetic layer that exhibited perpendicular anisotropy from chiral molecular adsorption. In future experiments, chiral molecules could be instead assembled directly on diamond surfaces, in close proximity to NV centers, with externally driven charge transfer to generate spin polarization.^{393,415–418} Adsorbed molecules supporting charge- and spin-polarized electrons would induce both electric and magnetic fields at the NV position, enabling new methods for characterization of CISS that could provide novel mechanistic insight.

6.5 Catalysis

As previously mentioned, solid-state NMR is a powerful tool for studying the structure of heterogeneous catalysts⁴¹⁹ due to advancements in magnetic-field strength,³⁴⁹ fast MAS,³⁴⁸ and dynamic nuclear polarization (DNP).⁴²⁰ However, it is often unclear whether the relevant, active species are observed since the working conditions of most catalysts include either high temperatures or pressures, which differ dramatically from standard measurement conditions.⁴²¹ Consequently, the development of techniques for variable temperature and pressure operando NMR⁴²² are viewed as an important step towards *in situ* characterization of catalytic materials. Such schemes are still limited to probing sensitive NMR nuclei that are in high abundance. Moreover, the detection of active sites in supported single-site catalysts is not compatible with this technique since such studies rely on solid-effect DNP and therefore must be performed at liquid-nitrogen temperatures in frozen glassy matrices of radical solution.⁴²³ In contrast, the high pressure and temperature stability of diamond, in combination with exquisitely sensitive NV sensors, could enable detection of dilute, insensitive nuclear species at relevant catalytic working conditions. For such experiments, single-site catalysts would be prepared in the vicinity of NV sensor spins using a surface-organometallic chemistry.⁴²⁴ The conventional metal-oxide support (e.g., SiO₂, Al₂O₃) could be replaced either by well-defined diamond surface terminations with controllable densities of anchoring sites (e.g., hydroxyls or amines) or by a thin layer of oxide.³²¹ The latter option would utilize the original grafting chemistry at the cost of larger NV-sample distances, as exemplified in Fig. 13 for selected heterogeneous olefin-metathesis catalysts.⁴²⁴ Subsequently, structural changes resulting from catalytic reactions (e.g., loss of a ligand or change in oxidation state of the metal) would be detected using the NV center. Notably, while the large chemical-shift range and quadrupolar nature of many interesting NMR-active metals (e.g., ¹⁹⁵Pt, ⁷¹Ga) are a major challenge in conventional NMR spectroscopy, they could serve as a resource for NV-center sensing.

7 Outlook

NMR and EPR spectroscopy of molecules are powerful tools for elucidating details of chemical structure, intermolecular interactions, and chemical reactions. The experimental approach wherein traditional inductive detectors are replaced with NV centers in diamond has facilitated highly sensitive and localized spectroscopy, allowing for detection of electron and nuclear spins in external targets at the single- or few-spin level. Encouragingly, vast improvements in measurement sensitivity have been obtained through advances in diamond surface engineering that reduce charge instability and decoherence for shallow emitters. In addition, novel methods for chemical functionalization of diamond allows for deterministic, covalent attachment of target molecular species.

Despite this impressive progress, additional experimental challenges must also be overcome. For instance, the stability of molecular films or of hierarchically ordered structures in biomolecules may be compromised by extended exposure to laser- and microwave-induced heating. Nevertheless, use of low laser power as well as reduced experimental duty cycles may help to prevent ablation of specifically bound molecules during extended measurement times. Likewise, reduced microwave duty cycles, or elimination of microwave sources entirely (*e.g.*, for relaxometry measurements) can mitigate heating issues. In addition, current detection sensitivities necessitate long integration times, placing limits on reaction monitoring or tracking of transient paramagnetic intermediates. Greater control over molecular density, orientation, and binding configurations at diamond surfaces will circumvent rapid diffusion of analytes into and out of NV sensing volumes, allowing for longer measurements. Moreover, motional dynamics and thermal fluctuations in large molecules induce signal broadening, complicating the extraction of structural and functional information and localized imaging of surface spins. Depending on the sensing application, immobilization approaches that restrict motional degrees of freedom can be employed to reduce spectral broadening. Finally, despite the exquisite sensitivity and spatial resolution, NV-center spectroscopy cannot achieve the spectral resolution of conventional spectroscopy methods. Indeed, typical magnetic-field biases applied in NV experiments are on the order of *ca.* 10^{-3} – 10^{-1} T, compared to *ca.* 10^0 – 10^1 T in conventional NMR. Therefore, a 5 ppm ^1H chemical shift, easily resolved in conventional NMR with an operating field strength of, *e.g.*, 600 MHz, would result in an absolute shift of <1 Hz at 20 mT. However, novel NV approaches including homonuclear decoupling sequences,²⁷ ensemble measurements,²⁸ or hyperpolarization techniques²⁹ provide promising paths forward.

In conclusion, advances in diamond surface engineering and chemical functionalization have facilitated landmark advances in nanoscale NMR and EPR using NV centers. Moving forward, the simultaneous immobilization of chemical analytes and preservation of NV sensing properties represents a critical step toward single-spin, coherent detection in chemically and biologically relevant systems. Efforts to overcome these

challenges will benefit from the interdisciplinary nature of this research field, which lies at the intersection of surface chemistry, materials science, and quantum metrology. Motivated by the promise of new insights into molecular structure, spin transport, and reaction monitoring, the utility of NV-center sensing for the chemical sciences has only just begun to be realized.
