Electronic transitions of molecules: vibrating Lewis structures

Yu Liu,^a Philip Kilby,^b Terry J. Frankcombe^c and Timothy W. Schmidt^{id}*^a

Since the conception of the electron pair bond, Lewis structures have been used to illustrate the electronic structure of a molecule in its ground state. But, for excited states, most descriptions rely on the concept of molecular orbitals. In this work we demonstrate a simple and intuitive description of electronic resonances in terms of localized electron vibrations. By partitioning the $3N$ -dimensional space of a many-electron wavefunction into hyper-regions related by permutation symmetry, chemical structures naturally result which correspond closely to Lewis structures, with identifiable single and double bonds, and lone pairs. Here we demonstrate how this picture of electronic structure develops upon the admixture of electronic wavefunctions, in the spirit of coherent electronic transitions. We show that π - π^* transitions correspond to double-bonding electrons oscillating along the bond axis, and n - π^* transitions reveal lone-pairs vibrating out of plane. In butadiene and hexatriene, the double-bond oscillations combine with in- and out-of-phase combinations, revealing the correspondence between electronic transitions and molecular normal mode vibrations. This analysis allows electronic excitations to be described by building upon ground state electronic structures, without the need for molecular orbitals.

1 Introduction

The chemist's picture of electronic structure is highly adaptable. For depicting ground state structures, it is usual to draw one or more Lewis structures, where valence electrons are assigned to bonds, or lone pairs.¹ The theoretical foundation of this picture is accounted for by valence bond theory, which is therefore more intuitive than the molecular orbital theory approach.² However, the understanding of excited states of molecules is almost always within the framework of excitations of electrons within molecular orbitals (MOs). The MO approach is particularly prevalent in the description of conjugated systems, where the delocalized electronic orbitals are separated by their symmetry in π and σ representations.³

For accurate calculations of excited states, for reasons of computational simplicity one is left with no choice but to take an approach based on molecular orbitals. However, as is well known, the calculated wavefunctions are invariant to the choice of orbitals, providing they span the same Hilbert space. Also, interpretations of electronic structure based on orbitals alone ignore the effect of (anti)symmetry: In many cases the S_1 and T_1 states are largely described by the same orbital occupancy, but have entirely different wavefunctions. Furthermore, interpreting the excited-state wavefunction can be problematic when the

transition is described by a multitude of single and double (or higher) excitations from the reference wavefunction.⁴

It is desirable to arrive at a simpler view of excited states based on accurately calculated and correctly antisymmetrised wavefunctions, ideally providing insight in an intuition-free manner. Recently, we reported a partitioning of the $3N$ -dimensional ground-state wavefunction into "tiles".⁵ The equivalent tiles, which do not overlap, are themselves $3N$ -dimensional objects and are related by permutation of like-spin electrons. Each tile contains all the information of the entire wavefunction, since other tiles are merely repeats related by the interchange of electrons of the same spin: Tiles are positive or negative depending on the sign of the permutation. We and others demonstrated that if the boundaries between like-signed tiles are defined by a Voronoi diagram, with sites given by the centre-of-mass of the tile, the tiles reproduce Lewis structures of molecules and the double-quartet structures of Linnett.⁵⁻¹⁰ Further, by following the tiles as a function of a reaction coordinate, one obtains electron movements akin to the "curly arrows" beloved of organic chemists.¹¹ Our procedure to obtain these structures is designated dynamic Voronoi Metropolis sampling (DVMS). Fig. 1 shows calculated DVMS structures for some simple molecules: only one spin is shown, since they are both equivalent in these closed-shell species. The DVMS structures exhibit core electrons, single-bonding electrons, double "banana"-bonding electrons and non-bonding lone-pairs, corresponding closely to the Lewis structures.^{9,10}

The ground-state electronic wavefunction only contains nodes engendered by the antisymmetry required to satisfy

Fig. 1 The RHF/6-31G(d) DVMS structures for formaldehyde, water, and ethylene, and corresponding Lewis structures. DVMS yields lone pairs and core electrons, and represents double bonds as a pair of “banana bonds”. Electron positions are indicated with small gold spheres with larger spheres representing atomic positions. Only one spin is shown (both are equivalent).

Fermi–Dirac statistics. The tiles themselves are nodeless. Excited-state wavefunctions also obey Fermi–Dirac statistics, and thus will also exhibit tiling. However, they will exhibit more nodes, and/or different nodes to the ground state.^{12,13} The excited-state wavefunction can thus also be explored by the DVMS procedure, but with nodes within the tiles.

In this work, we present an approach to describing molecular electronic transitions inspired by the time-dependence of coherent electronic transitions. If the time-dependent Schrödinger equation is solved for a molecule subject to an oscillating electric field, the electronic wavefunction, originally in the ground state, will evolve such that after the perturbation it can be described by a sum over electronic states. If the angular frequency, ω , of the oscillating electric field is well matched to the energy difference between the ground and excited state (resonance condition, $\hbar\omega \approx \Delta\varepsilon$), then the resulting wavefunction will be an admixture of the ground and the excited state. This mixed state is time-dependent, and exhibits “quantum beats”.

Here we show that, within the ground state tile, the average electron positions can be plotted as a function of phase, ωt , for a wavefunction mixed between the ground and excited state of interest. The resulting electron motions reveal the connection between classical vibrational motion and electronic spectroscopy.

2 Methods

2.1 Formalism

Energy eigenstates are “stationary” in that the observables are time-independent. However, a state that is written as an

admixture of one or more energy eigenstates evolves in time, exhibiting “quantum beats”. In order to maximize the magnitude of the quantum beats, we calculated the trajectory of the electron density for a maximally mixed wavefunction,

$$\Psi(\mathbf{x}, t) = \frac{\Psi_i(\mathbf{x}) + \exp(-i\omega t)\Psi_f(\mathbf{x})}{\sqrt{2}} \quad (1)$$

where $\Psi_i(\mathbf{x})$ and $\Psi_f(\mathbf{x})$ are respectively the initial and final electronic wavefunctions. The energy of the initial wavefunction is set arbitrarily to zero. The final-state energy is $\varepsilon = \hbar\omega$. In this work we are interested in analysing wavefunction changes for excitations from the ground state, so Ψ_i and Ψ_f are the wavefunctions for the ground and excited states, respectively. We use Ψ_i to define the tiling of $\Psi(\mathbf{x}, t)$ and for convenience we here use Ψ_i and Ψ_f that are normalised over a single tile.

The centroid of the tile (a $3N$ vector $\bar{\mathbf{x}}$) evolves as

$$\begin{aligned} \bar{\mathbf{x}}(t) &= \int_R \Psi^*(\mathbf{x}, t)\mathbf{x}\Psi(\mathbf{x}, t)d\mathbf{x} \\ &= \frac{\bar{\mathbf{x}}_i + \bar{\mathbf{x}}_f}{2} + \cos(\omega t)\mathbf{x}_{fi} \end{aligned} \quad (2)$$

where R is the region defining a single tile, $\bar{\mathbf{x}}_i$ and $\bar{\mathbf{x}}_f$ are the position expectation values of Ψ_i and Ψ_f over the tile and $\mathbf{x}_{fi} = \int_R \Psi_f \mathbf{x} \Psi_i d\mathbf{x}$. The centroid thus oscillates about the average density centroids of the two states. The amplitude of this oscillation, \mathbf{x}_{fi} , may be partitioned in an analogous way to the DVMS centroid positions, as

$$\mathbf{x}_{fi} = \begin{pmatrix} \mathbf{r}_1 \\ \mathbf{r}_2 \\ \vdots \\ \mathbf{r}_3 \end{pmatrix}, \mathbf{r}_j \in \mathbb{R}^3 \quad (4)$$

where the \mathbf{r}_j are the N individual electron displacements. Their sum is the electronic transition dipole moment, $\boldsymbol{\mu}_{fi}$, divided by the elemental charge, e .

$$\sum_j \mathbf{r}_j = \frac{\boldsymbol{\mu}_{fi}}{e} \quad (5)$$

As such, the oscillation direction and amplitude is directly related to the polarization and strength of the electronic transition.

2.2 Wavefunctions

All electronic wavefunctions were calculated using the FIREFLY program,¹⁴ which is largely based on the GAMESS package.¹⁵ Unless where stated, the 6-31G(d) basis was used. Ground and excited state wavefunctions were calculated at the CAS-CI level using ground state RHF orbitals, except in the case of ethylene.

3 Results and discussion

The first excited state of ethylene, C_2H_4 , has been the subject of controversy. The so-called V state is somewhat difficult to calculate, with large scale calculations settling on a vertical

excitation energy of 7.88 eV, and a spatial extent with respect to the molecular plane of $\langle \Psi_V | x^2 | \Psi_V \rangle \approx 18 - 20a_0^2$. Wu and co-workers obtained a vertical excitation energy of 8.01 eV and a spatial extent of $\langle x^2 \rangle = 19.14a_0^2$ with a compact valence bond wavefunction and a triple zeta basis set which included diffuse functions.¹⁶ Here we similarly adopt a polarized basis set with diffuse functions, and an active space of four orbitals spanning the symmetries of the carbon-carbon σ , π , π^* , and σ^* orbitals in the D_{2h} point group. Calculated excited-state energies and second moments are given in Table 1 for the experimental geometry from ref. 16, exploring the effect of the treatment of electron correlation. CASSCF/TZV(2d,f;p)+ wavefunctions with a (4,4) active space were used for the DVMS analysis as an efficient means of accessing a wavefunction of comparable accuracy to the BOVB-5/aug-cc-pVTZ results of ref. 16.

While we cannot say how the position of a particular electron evolves (they are all equivalent), DVMS allows us to inspect how the average position of each electron evolves in time from the perspective of a single wavefunction tile. In DVMS, the σ - π description of the double bond is replaced by a “banana bond” picture,¹⁷ with one electron of each spin lying above and below the bond axis (Fig. 1). Fig. 2 (left) depicts the trajectory of the tile centroid of ethylene as a function of phase, ωt . The α (up-spin) and β (down-spin) electrons have identical average positions, so only one spin-set is shown. Upon admixture of the N and V wavefunctions (S_0 and S_1 states), all four electron positions (2α and 2β) of the double bond execute oscillatory motion along the C=C axis. The core and C-H σ -bonding electrons are not significantly affected by the electronic transition, as intuitively expected. The excitation traditionally depicted π - π^* corresponds to the “banana-bonding” electrons vibrating along the bond axis.

Since the motion of the centroid is described by an oscillation (eqn (3)), it may be illustrated by vectors indicating the motions of particular positions ($\{r_j\}$, eqn (4)), as is routine for vibrational normal modes of molecules. This depiction is shown on the right of Fig. 2, succinctly representing the correlated motion of the banana-bonding electrons in the C=C bond in the N - V transition. With this connection made, it is interesting to explore how other vibrational modes might correspond to different excited states.

In the MO picture, the singlet and triplet states derived from the same π - π^* excitation are crudely described by the same determinants, but with a change of sign:

Fig. 2 Left: The DVMS tile centroid of ethylene as a function of phase, ωt (eqn (3)). The wavefunction is mixed between the ground ‘N’ state and excited ‘V’ state (eqn (1)). Only one spin-set is shown, since both spins move identically. Right: The electron positions for the mid-point of the vibration (gold spheres), $\bar{x} = (\bar{x}_i + \bar{x}_j)/2$, and the displacement vector x_{fi} (blue arrows).

$$\begin{aligned}\Psi_{S_1} &\approx |\phi_\pi \overline{\phi_{\pi^*}}| + |\phi_{\pi^*} \overline{\phi_\pi}| \\ \Psi_{T_1} &\approx |\phi_\pi \overline{\phi_{\pi^*}}| - |\phi_{\pi^*} \overline{\phi_\pi}|\end{aligned}\quad (6)$$

This is the case for many, if not most, chromophores. So, where the excited singlet (Fig. 2) has the α and β electrons vibrating in-phase, the ($m_s = 0$) triplet state has the α and β electrons vibrating out-of-phase, thereby exhibiting no electronic transition dipole moment. The DVMS structure and displacement vector for the forbidden $T_1 \leftarrow S_0$ transition are shown in Fig. 3.

The present treatment may be extended to other chromophores. Formaldehyde is isoelectronic with ethylene, but exhibits a richer electronic spectrum on account of the involvement of the non-bonding, “lone pair” electrons. There are three low-lying excited states: π - π^* , and two n - π^* states.¹⁸ From the standpoint of the MO approach, the latter two can be considered excitations from symmetry-adapted combinations of lone pairs giving rise to $a_1 \rightarrow b_1$ and $b_2 \rightarrow b_1$ transitions to 1B_1 and 1A_2 excited states respectively. The latter is of considerable photophysical interest.¹⁹ The DVMS picture is shown in Fig. 4.

Rotation about the z -axis of formaldehyde transforms as the a_2 representation in the C_{2v} point group. Since the ground state is 1A_1 , the transition moment to the 1A_2 state also transforms

The α and β electrons oscillate out of phase about the same midpoint, so there is no transition dipole moment.

Fig. 4 The electron positions for the mid-point of the vibration, $\bar{x} = (\bar{x}_i + \bar{x}_j)/2$, and the displacement vectors x_{fi} for the wavefunction mixed between the 1^1A_1 (ground), and 1^1A_2 , 2^1A_1 and 1^1B_1 excited states of formaldehyde. The vector length is doubled for clarity.

as a_2 and the transition is electric-dipole forbidden, but magnetic-dipole allowed. The rotation of charge is evident in Fig. 4: the lone-pair electrons rotate out of plane. Surprisingly, at this level of theory ((6,4) CAS-CI) there is also considerable out-of-plane motion of the C–H bonding electrons.

The $2^1A_1 \leftarrow 1^1A_1$ transition is analogous to the $\pi-\pi^*$ transition of ethylene, where the double-bonding electrons oscillate along the molecular symmetry axis. Finally, the $1^1B_1 \leftarrow 1^1A_1$ transition is represented by oscillation of the lone-pair (and C–H bonding) electrons out of plane.

trans-Butadiene is normally drawn with two conjugated double bonds, and its DVMS structure bears this out. Like for ethylene, accurate calculations for excited states of *trans*-butadiene require attention to correlation and basis set.^{20–23} The present wavefunctions were calculated at the (4,4) CAS-CI/6-31G(d) level, and we do not expect accurate energies or state-ordering. However, for ethylene, the qualitative nature of the excitation was not found to be sensitive to the level of theory.

The two lowest excited states are 1^1B_u and 2^1A_g (C_{2h} point group). The 2^1A_g state of *trans*-butadiene is dark, being described by two triplet configurations, one on each double bond.^{24–26} We do not investigate this state here, since it is not amenable to a treatment rooted in time-dependent quantum mechanics. The lowest bright excited state is 1^1B_u .

The DVMS picture of the electron vibration arising from the 1^1B_u wavefunction mixed with the 1^1A_g ground state is shown in Fig. 5. Here, eight electrons, four from each double bond, oscillate along the C=C bonds, all in-phase. Since the individual C=C bond transition dipoles add, the $1^1B_u \leftarrow 1^1A_g$ transition is seen to be strongly allowed.

Fig. 5 The electron positions for the mid-point of the vibration, $\bar{x} = (\bar{x}_i + \bar{x}_j)/2$, and the displacement vectors x_{fi} , for the $1^1B_u \leftarrow 1^1A_g$ and $3^1A_g \leftarrow 1^1A_g$ transitions of *trans*-butadiene. The vector length is doubled for clarity.

The question naturally beckons as to whether there is an excitation described by the out-of-phase excitation of the two double bonds. In *trans*-butadiene, such a transition would be forbidden, since the transition dipoles of the two double bonds cancel.

At the present level of theory this transition was found to be the $3^1A_g \leftarrow 1^1A_g$ transition. The corresponding electron vibration is illustrated in Fig. 5. It stands to reason that this state would lie higher in energy than the bright state, since its opposing dipoles lie end-to-end, analogous to a molecular exciton (J-aggregate).²⁷ This is not the $2^1A_g \leftarrow 1^1A_g$ transition, as one might expect, because the 2^1A_g state is the dark triplet-pair state mentioned above. The exact nature of the 2^1A_g state is a subject of ongoing investigation.^{22,28}

Like in *trans*-butadiene, the lowest excited state of *trans,trans*-hexatriene is described as a dark, doubly excited triplet pair.²⁹ The next lowest-energy states calculated are 1^1B_u , 2^1A_g and 2^1B_u . The electron vibrations corresponding to excitations to these states from mixing CAS-CI wavefunctions are illustrated in Fig. 6. The lowest-energy bright state is 1^1B_u , and the electron vibration is the in-phase combination of double-bond oscillations. The length of the displacement vector x_{fi} is larger for the central double bond, compared to the outer bonds.

The excitation to the 3^1A_g state is dipole forbidden, and the displacement vector shows the outer double bonds vibrating out-of-phase, such that the local dipoles cancel. The excitation to the 2^1B_u state is symmetry allowed, but the displacement vectors partially cancel. The vibration of the central bond is out of phase with those of the outer bonds.

Fig. 6 The electron positions for the mid-point of the vibration, $\bar{x} = (x_i + x_f)/2$, and the displacement vectors x_{fi} , for the $1^1B_u \leftarrow 1^1A_g$, $3^1A_g \leftarrow 1^1A_g$ and $2^1B_u \leftarrow 1^1A_g$ transitions of *trans,trans*-hexatriene. The vector length is doubled for clarity.

The three states calculated for hexatriene are in keeping with the analogy between molecular vibrational modes and electronic transitions. Further, the magnitudes of the vectors are as intuitively expected. The out-of-phase vibration of the outer bonds for the transition to the 3^1A_g state necessitates a zero component for the central bond. The outer bonds make a correspondingly smaller contribution to the 1^1B_u states.

Extending the analogy of coupled oscillators to longer polyenes, it is expected they all exhibit a 1^1B_u state where the double-bonds oscillate in-phase, giving rise to a large transition dipole. As polyenes increase in length, the dipole-dipole coupling of each double-bond oscillation will lower the frequency of the resonance. The naturally occurring β -carotene has 11 conjugated double bonds, and a strong transition at 2.6 eV. For the polyenes, the 1^1B_u band converges to an energy near 2 eV for long chains ($n \geq 20$).³⁰

This picture of electronic transitions in conjugated systems can be extended to cyclic systems. Cyclic polyenes require special attention owing to the emergence of resonance structures. Indeed, in a forthcoming publication we will demonstrate that the most appropriate description of benzene is a superposition of Kekulé structures where α and β electrons are correlated: They occupy alternate Kekulé structures. In this picture, the in-phase vibration of the double bonds generates a cyclic motion of charge and therefore no net dipole. This corresponds to the transition to the 1^1B_{1u} (S_2) state. Transitions to the bright degenerate E_{1u} states (S_3) are described by vectors which have magnitudes given by $\cos \theta$ and $\sin \theta$, where θ is the angle describing the position of the double bond on the ring. The $S_1 \leftarrow S_0$ transition is forbidden: The S_1 state of benzene is related to S_0 by a change in relative phase of the comprising (staggered-spin) Kekulé structures, and as such the tile centroids are unmoved.

4 Conclusions

Using the dynamic Voronoi Metropolis sampling procedure (DVMS), we defined wavefunction tiles for a range of chromophores and showed that the centroids corresponded closely with the canonical Lewis structures. We investigated the centroid of the electron density in the tile for time-dependent wavefunctions mixed between the ground and various excited states and found that the centroid oscillates with an amplitude proportional to the transition dipole moment. For polyenes, where the DVMS describes the structure as isolated double “banana bonds”, it was found that transitions to various excited states may be described as the in- and out-of-phase vibrations of the individual double bonds. The most intense transition is characterized by an in-phase vibration of the double bonds. We anticipate that this method will allow a variety of electronic transitions to be interpreted in terms of electro-dynamically-induced vibrations of the ground state electronic structure. Because this viewpoint does not require the invocation of molecular orbitals, it allows the essence of electronic spectroscopy to be described outside this paradigm.
