Previously, we and others have used cantilever-based techniques to measure droplet friction on various surfaces, but typically at low speeds $U<1~{\rm mm~s^{-1}}$; at higher speeds, friction measurements become inaccurate because of ringing artefacts. Here, we are able to eliminate the ringing noise using a critically damped cantilever. We measured droplet friction on a superhydrophobic surface over a wide range of speeds $U=10^{-5}-10^{-1}~{\rm m~s^{-1}}$ and identified two regimes corresponding to two different physical origins of droplet friction. At low speeds $U<1~{\rm cm~s^{-1}}$, the droplet is in contact with the top-most solid (Cassie-Baxter), and friction is dominated by contact-line pinning with $F_{\rm fric}$ force that is independent of U. In contrast, at high speeds $U>1~{\rm cm~s^{-1}}$, the droplet lifts off the surface, and friction is dominated by viscous dissipation in the air layer with $F_{\rm fric} \propto U^{2/3}$ consistent with Landau-Levich-Derjaguin predictions. The same scaling applies for superhydrophobic and underwater superoleophobic surfaces despite their very different surface topographies and chemistries, i.e., the friction scaling law derived here is universal.

1 Introduction

One conspicuous feature of wetting phenomena is the great diversity of timescales and contact-line speeds involved $^{1-3}$. A typical millimetric water droplet sitting on a surface evaporates within an hour, which translates to the contact line retracting at a speed of $\sim \mu m \ s^{-1} \ 4,5$; in contrast, the same droplet bounces off a superhydrophobic surface within ~ 10 ms with a contact-line speed of $\sim m \ s^{-1} \ 6-8$. To fully capture the wetting properties of a surface is therefore a daunting experimental task, requiring us to probe droplet friction—from the slowest to the fastest—over some 6 orders of magnitude.

Previously, we and others introduce cantilever-based techniques to measure droplet friction $^{9-18}$. While the various techniques vary in their detailed implementations, they all rely on the same physical principle: a droplet (typically millimetric in size) is attached to a cantilever of known spring constant, and droplet friction can be determined by quantifying the cantilever deflection. Cantilever-based techniques have proven to be a simple but powerful tool to measure droplet friction with high sensitivity and precision ($\sim 10\,\mathrm{nN}$ force resolutions $^{14-16}$) over a wide range of surfaces—including superhydrophobic 15,16 , underwater superoleophobic 14 , and lubricated surfaces 12 —and with many advantages over traditional contact angle measurements 2,19,20 .

However, cantilever-based techniques are typically confined to low droplet speeds $U < 1 \, \mathrm{mm \ s^{-1}}$. This is because at higher speeds, the cantilevers suffer from ringing artefacts resulting in inaccurate friction measurements. For example, see Supporting Fig. S2b in a recent publication by Backholm *et al.* (2024) ¹⁸, where ringing is clearly visible. In this work, we eliminate ringing by using a critically damped cantilever, greatly improving the measurement accuracy and signal-to-noise ratios at high speeds $U > 10 \, \mathrm{cm \ s^{-1}}$; friction forces can also now be measured with the fastest theoretical time resolution of $1/\omega_o$, where ω_o is the natural frequency of the cantilever.

With our setup, we are able to measure droplet friction $F_{\rm fric}$ on superhydrophobic surfaces over an unprecedented range of speeds from 10 $\mu {\rm m~s^{-1}}$ to 30 cm s⁻¹, spanning over 4 orders of magnitude. At low speeds $U < 1~{\rm cm~s^{-1}}$, $F_{\rm fric}$ is dominated by contact-line pinning and is independent of U, consistent with previous reports 13,21 . Here, we identify a new friction regime, where $F_{\rm fric} \propto U^{2/3}$ for high $U > 1~{\rm cm~s^{-1}}$ which can be attributed to viscous dissipation in the air layer, consistent with Landau-Levich-Derjaguin (LLD) formulations 22,23 . We further show that the derived scaling law is universal across different superhydrophobic and underwater superoleophobic surfaces.

Our approach to fabricating critically damped cantilevers—by enclosing the cantilever inside a column of viscous liquid (e.g., water-glycerin mixture)—is simple to implement and can be used to probe the physical origins of droplet friction on various surfaces, uncovering the mechanisms behind different wetting phenomena.

2 Materials and methods

2.1 Surface preparations

Superhydrophobic Glaco samples were made by spray coating clean glass slides with a layer of hydrophobic nanoparticles (Glaco Mirror Coat Zero, Soft 99 Co). The samples were then placed vertically to dry for one hour before use, following the manufacturer's instructions. Black silicon surface was fabricated as described previously in the literature ^{15,24}. Scanning electron micrographs of the two surfaces can be found in Fig. 6A.

Underwater superoleophobic surfaces were prepared by grafting glass slides with zwitterionic poly(sulfobetaine methacrylate) brush surfaces. Details can be found in our previous publication ¹⁴. Topography of the brush layer can be found in Fig. 6B as measuring using an atomic force microscope.

Table 1 Properties of the superhydrophobic surfaces, where $\Delta\cos\theta = \cos\theta_{\rm rec} - \cos\theta_{\rm adv}$.

Surface	$\theta_{ m adv}$	$\theta_{ m rec}$	$\Delta\cos\theta$
Glaco	172°	168°	$1.2 \times 10^{-2} \\ 1.0 \times 10^{-2}$
Black silicon	174°	170°	

2.2 Contact angle measurements

This article is licensed under a Creative Commons Attribution 3.0 Unported Licence.

Open Access Article. Published on 29 1446. Downloaded on 05/03/46 04:17:07

Contact angle measurements were performed for 10 μ L water drops using a commercially available instrument (Kruss DSA 100) at room temperature (21°C, 60% humidity). To measure advancing and receding contact angles (θ_{adv} and θ_{rec}), water was pumped in and out at a rate of 0.2 μ L s⁻¹. Results of the contact angle measurements are summarized in Table 1.

Errors in the contact angle measurements $\delta\theta$ for the superhydrophobic surfaces are likely to be large. For $\theta=175^\circ$, $\delta\theta$ can be as large as 5° , which translates to an error in $\Delta\cos\theta$ measurement of $\sqrt{2}\sin\theta\,\delta\theta\sim10^{-2}$. As discussed in our previous work², contact-line friction is better characterized by the quantity $\Delta\cos\theta=\cos\theta_{\rm rec}-\cos\theta_{\rm adv}$, rather than the more conventional $\Delta\theta=\theta_{\rm adv}-\theta_{\rm rec}$. Contact angle measurements cannot be done for an oil droplet on zwitterionic surface under water because it has contact angles of 180° and zero $\Delta\cos\theta^{14}$.

2.3 Measuring friction

We used a cantilever-based method to measure the friction force $F_{\rm fric}$ acting on the droplet (Fig. 1A). Briefly, a water droplet (volume V=15–30 μ L) is attached by capillarity to cylindrical tubes (which act as cantilevers) of different dimensions, materials, and spring constants, as summarized in Table 2. The steel cylindrical tube is solid, while the acrylic tube is hollow with an inner diameter of 0.3 mm. Here, the droplet diameter $2R=(6V/\pi)^{1/3}=3$ mm is much larger than that of the cantilever d<0.4 mm, such that the droplet geometry is minimally affected. At the same time, R is smaller than the capillary length of 2.7 mm, so that the droplet remains spherical.

The surface was moved back-and-forth at a controlled speed of $U = 10^{-5}$ – 10^{-1} m s⁻¹ using a motorized stage. F_{fric} can then be

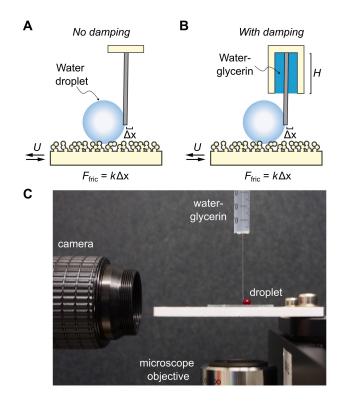

Fig. 1 Droplet Force Apparatus (DFA). Schematic of instrument used to measure droplet friction on superhydrophobic surface (A) without damping and (B) with damping. (C) Photograph of DFA setup with damping. Food dye is added to the water droplet for clarity, but it is not used in our experiments.

Table 2 Cantilever/cylindrical tube properties. d is the tube outer diameter, L is its length, k the spring constant, and b_0 the intrinsic damping coefficient without any liquid column, i.e., in air.

Material	d (mm)	L (cm)	$k \text{ (mN m}^{-1})$	$b_0 \; ({\rm mg \; s^{-1}})$
Acrylic	0.36	9	14	47 ± 5
Acrylic	0.36	6	55	105 ± 20
Steel	0.15	5.5	144	49 ± 5

inferred from the cantilever deflection Δx (averaged over several cycles), since $F_{\rm fric}=k\Delta x$ where k=14–144 mN m $^{-1}$ is the flexular spring constant. Δx was recorded using a high speed camera (up to 1000 fps, Krontech Chronos 2.1) and determined using a cross-correlation algorithm with micron resolutions. The entire setup was placed on an optical table and enclosed to minimise vibration and draught. This way, we can reduce the inherent instrument noise to $\Delta F_{\rm noise}=5$ nN and reliably measure forces as small as 10 nN. The inherent $\Delta F_{\rm noise}$ is obtained by measuring cantilever deflection in absence of any droplet motion.

We previously named this custom-built instrument the Droplet Force Apparatus (DFA) 14 , whose details can be found in our previous publications $^{12-14}$. An important innovation we introduced here is the addition of a damping system. We placed the cantilever coaxially inside a cylinder (with a much larger radius of 2.5 mm) filled with water-glycerin solution (Fig. 1B). By optimizing the glycerin concentration (and hence the liquid column viscosity η_c) and liquid column height H, we can achieve a critically damped

Access Article. Published on 29 1446. Downloaded on 05/03/46 04:17:07

system and measure $F_{\rm fric}$ with the fastest theoretical time resolution of $1/\omega_o$, where $\omega_o=\sqrt{k/m}$ is the natural frequency of the cantilever with an attached droplet of mass m. Critical damping is achieved when $b=\sqrt{4mk}$, i.e., the damping coefficient has to be tuned for specific droplet-cantilever combination for particular droplet mass m and the spring constant k. Here, the cantilever masses are much smaller than m and can be safely ignored.

The DFA setup can also be integrated with microscopy (specifically Reflection Interference Contrast Microscopy) to visualize the droplet base as shown in Fig. 1C.

2.4 Measuring Cantilever spring constant

The spring constant of the cantilever k can be determined using the added weight method 12,21 . We placed masses (e.g., microlitre-sized water droplets) of different weights W at the cantilever tip and measured the deflection Δz optically. The slope of W vs. Δz corresponds to k. k can also be obtained from the natural frequency ω_o . See details in Supporting Figure S1, S2 and Supporting Table S1.

2.5 Measuring damping coefficient *b* from free-decay oscillations

To measure the damping coefficient, we attached a solid mass with m=25–270 mg to the cantilever. We then applied a short impulse by blowing air to the attached mass using a blower ball. As long as $b/\sqrt{4mk} < 1$, the mass will perform an underdamped simple harmonic motion with an exponential decay envelope $\exp(-bt/(2m))$, from which we can derive b.

2.6 Visualizing droplet base

We used Reflection Interference Contrast Microscopy (RICM) to visualize the droplet base and the air film beneath it 12,14,25 . Briefly, we shone monochromatic light (wavelength $\lambda=561$ nm) from below and captured the reflection off the droplet's base using a high-speed camera (Photron Nova S20) fitted with a $5\times$ microscope objective. The air film gives rise to thin-film interference, i.e., dark and bright fringes as the light reflected off the water-air and air-solid interfaces interfere destructively and constructively with one another. Contact-line pinning (including its absence) can be clearly observed using this technique.

3 Results and Discussions

3.1 Ringing artefact in underdamped cantilever

We start by measuring droplet friction without the addition of any damping system on our custom-built instrument, which we named the Droplet Force Apparatus or DFA (Fig. 1A). Fig. 2A shows a typical force curve for a 25 μ L water droplet (mass m=25 mg) moving back and forth on a Glaco superhydrophobic surface at a controlled speed of U=0.1 mm s⁻¹ (3 cycles over a D=5 mm distance). In this case, DFA is able to accurately measure the friction force $F_{\rm fric}=1.0\pm0.1~\mu$ N (Fig. 2A). At this low speed, the droplet is in contact with the topmost solid fractions, and the observed force fluctuations $\Delta F_{\rm contact}=0.1~\mu$ N (Inset in

Fig. 2A) can be attributed to contact-line pinning at the receding edge (Supporting Video S1) and is significantly larger than the inherent instrument noise $\Delta F_{\rm noise} = 5$ nN; $\Delta F_{\rm contact}$ reflects the topographical heterogeneity of superhydrophobic surfaces, i.e., it is not an experimental artefact or noise.

In contrast, the observed force fluctuations $\Delta F_{\rm Gibbs}$ at higher speeds U=10 and 30 cm s $^{-1}$ are Gibbs ringing noise, an experimental artefact that should be eliminated (Fig. 2B and C). $\Delta F_{\rm Gibbs}$ oscillates at frequency $\omega_o \approx 20$ rad s $^{-1}$ and is associated with the failure of the underdamped cantilever to respond quickly enough to the droplet inertia ma, where m and a are the droplet's mass and acceleration. For U=10–30 cm s $^{-1}$ (Fig. 2B and C), $ma\sim mU\,\omega_o\approx 50$ –120 µN, much larger than $F_{\rm fric}=1$ µN, and we therefore observed Gibbs noise. In contrast, for U=0.1 mm s $^{-1}$ (Fig. 2A), $mU\,\omega_o\approx 50$ nN $\ll F_{\rm fric}$, and there was no Gibbs noise.

For $U=10~{\rm cm~s^{-1}}$, the initial $\Delta F_{\rm Gibbs}=1.3~\mu{\rm N}$ and is comparable to the actual friction force $F_{\rm fric}=1.9~\mu{\rm N}$. Fortunately, $\Delta F_{\rm Gibbs}$ decays within a couple of seconds to allow for reasonably accurate $F_{\rm fric}$ measurement. The ringing noise is exarcebated at an even higher $U=30~{\rm cm~s^{-1}}$ with $\Delta F_{\rm Gibbs}=3.7~\mu{\rm N}$, again comparable to $F_{\rm fric}=7.0~\mu{\rm N}$. However, this time $\Delta F_{\rm Gibbs}$ does not decay quickly enough and adversely impact the accuracy of friction measurements.

The required travel distance $D=U\Delta t$ quickly rises with increasing U. $F_{\rm fric}$ can be accurately measured with D=5 mm when U=0.1 mm s⁻¹ (Fig. 2A). However, when U=30 cm s⁻¹, friction measurements remain challenging even with D=20 cm (Fig. 2C). Without any damping system, friction measurements at high speeds are impossible for small sample sizes ~ 1 cm. In the next section, we will discuss how these limitations can be overcome by using a critically damped cantilever.

3.2 Designing critically damped cantilever

The damping coefficient b of the cantilevers can be obtained by observing the free decay oscillation of an attached solid mass m following a short impulse (Fig. 3A). For an underdamped system where $b/\sqrt{4mk}\ll 1$, the cantilever oscillates close to the natural frequency $\omega_o=\sqrt{k/m}$, which was observed experimentally for a wide range of k=14–144 mN m $^{-1}$ and m=25–270 mg (Fig. 3B). We also expect the oscillations to dampen with a decay envelope of the form $e^{-bt/(2m)}$, which was also borned out by experiments (Fig. 3C and D).

The damping coefficient $b=b_0+b_\eta$ has two components b_0 and b_η . b_0 is the intrinsic damping coefficient, whose physical origin is complex but is linked to the dissipation at the fixed point of the cantilever mounted to the top wall. Experimentally, b_0 can be obtained from the decay envelope in air (no liquid column). For the cantilever with k=14 mN m⁻¹, we obtained $b_o=55$ mg s⁻¹ (Fig. 3C, Top). On the other hand, b_η is the viscous component due to the liquid column, whose magnitudes can be tuned by changing the liquid column viscosity η_c (Fig. 3C) and/or the column height H (Fig. 3D). This allows us to continuously tune b from its intrinsic value of 55 mg s⁻¹ (Fig. 3C, Top) to a maximum value of 815 mg $^{-1}$ (Fig. 3D, bottom).

Fig. 3E summarizes the experimental b values for three differ-

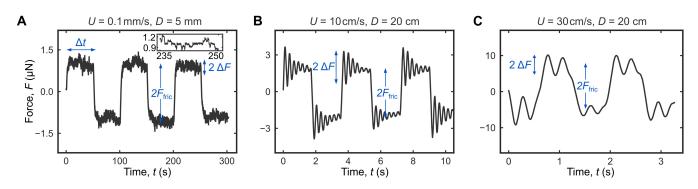

Fig. 2 Ringing artefact in droplet friction measurements (without damping). Friction force measurements are performed for 3 back-and-forth cycles at different speeds for a fixed droplet volume of 25 μ L. (A) At low speed $U=0.1~{\rm mm~s^{-1}}$, the observed ΔF is due to contact-line pinning. (B) At high speed $U=10~{\rm cm~s^{-1}}$, ΔF is primarily due to ringing artefact which decays with time. (C) At an even higher $U=30~{\rm cm~s^{-1}}$, ringing is even more prominent, and there is insufficient time for the noise to decay down. During every cycle, the travel distance each way are $D=U\Delta t=5~{\rm mm}$ for A, 20 cm for B and C; these distances are many times the size of the water droplet.

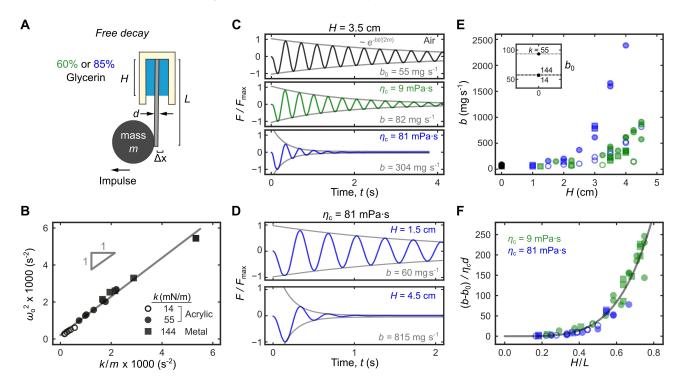

Fig. 3 Tuning the damping system in DFA. (A) The damping coefficient b can be measured by observing the free decay oscillation of an attached mass m following an impulse. (B) The oscillation frequency ω_o (in air) depends on the spring constant k and the attached mass m. For the same cantilever, b can be tuned by changing (C) the viscosity of the liquid column η_c and/or (D) the column height H. (E) b as a function of H for different cantilevers and liquid column viscosities (indicated by different markers and colours, respectively). Inset shows the damping coefficient b_0 when H=0, i.e., in air. (F) When correctly normalized, data in E collapse into a single master curve in Eq. 1 (gray line).

ent cantilevers (See Table 2 for detailed properties) as we vary the liquid column height H=0–4.5 cm and viscosities $\eta_c=9$, 81 mPa.s. When $b_\eta=b-b_0$ is normalized by $\eta_c d$ (where d is the cantilever diameter) and H normalized by the cantilever length L, the data in Fig. 3E collapse into a single master curve (Fig. 3F) that is well-described by the power law

$$b_{\eta}/(\eta_{\rm c}d) = 810(H/L)^{4.43}$$
 (1)

. We then used Equation 1 to optimize H and η_c to achieve critical

damping, i.e., $b=\sqrt{4mk}$. Since there are 5 variables $(b_\eta,\,\eta_{\rm c},d,H,$ and L) and 3 fundamental dimensions (mass, length, and time), Buckingham π theorem guarantees that there can only be 5-3=2 dimensionless groups, which we have chosen here to be $b_\eta/(\eta_{\rm c}d)$ and H/L. The fact that $b_\eta/(\eta_{\rm c}d)$ scales with H/L suggests that the hydrodynamic damping is primarily due to stokes flow in the liquid column, i.e., low Reynolds number flow 26 ; this is contrast to damping in Atomic Force Microscope cantilevers where it is dominated by high Reynolds number flow 27 . To rigorously justify the empirical fit in Equation 1 requires significant mathematical modelling outside the scope of this study.

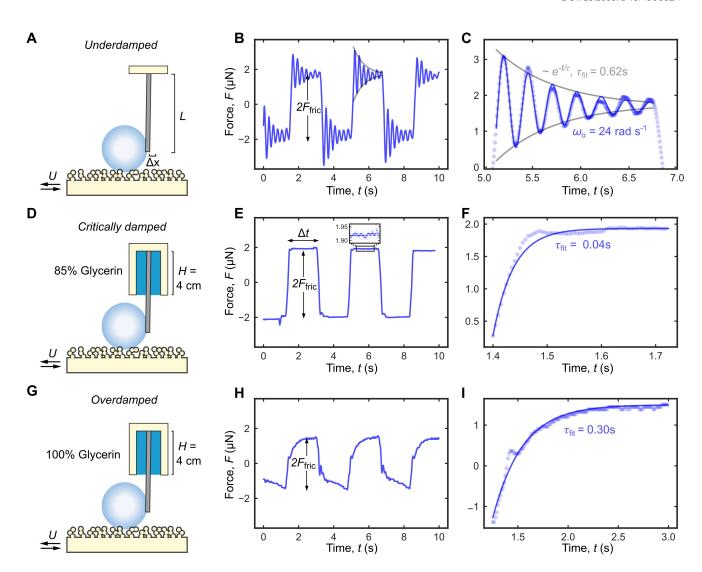

Fig. 4 Cantilever systems with different dampings. We measured friction $F_{\rm fric}$ for 20 μL droplets at a fixed speed of 10 cm s⁻¹. (A) When using a cantilever (k=14 mN m⁻¹) with no added damping, the system is underdamped, (B) and the force curve has the characteristic ringing artefact with (C) a decay time $\tau=0.62$ s. (D) When filled with H=4 cm of 85% glycerin mixture, the system is close to critically damped. (E) There is no ringing artefact, (F) and the system has a response time close to the theoretical maximum $\tau=1/\omega_0$. (G) When replaced with 100% glycerin, the system is overdamped. (H) There is no ringing noise, (I) but the response time $\tau=0.3$ s is significantly larger than $1/\omega_0$.

Table 3 Experimental parameters and results in Fig. 4. b is calculated using Equation 1. The droplet mass m=20 mg and the spring constant k=14 mN m⁻¹ in all experiments. Error in $F_{\rm fric}$ is based on standard deviation for the last 0.5 second of the force curve.

Cases	$b \text{ (mg s}^{-1}\text{)}$	$b/\sqrt{4mk}$	τ_{theor} (s)	$\tau_{\rm fit}$ (s)	$F_{\rm fric}$ (μ N)
A–C	50	0.04	2m/b = 0.8	0.62	$1.7{\pm}0.2$
D–F	700	0.7	$1/\omega_o = 0.037$	0.04	$1.93 {\pm} 0.01$
F–H	7000	7	b/k = 0.5	0.3	$1.50 {\pm} 0.01$

To illustrate the importance of using a critically damped cantilever, we performed friction measurements at a relatively high $U=10~{\rm cm~s^{-1}}$ using the same droplet volumes ($V=20~{\rm \mu L}$ and $m=20~{\rm mg}$) and cantilever ($k=14~{\rm mN~m^{-1}}$ and $\omega_o=\sqrt{k/m}=24~{\rm rad~s^{-1}}$), but with three different damping coefficients $b=50,700,7000~{\rm mg~s^{-1}}$ corresponding to underdamped, critically damped (or nearly so), and overdamped cases (Fig. 4). The underdamped case is just a cantilever with no liquid column, while the criti-

cally damped and overdamped cases are achieved by enclosing the cantilever with 85% and 100% glycerin of column height $H=4~\rm cm.$ $b/\sqrt{4mk}=0.04$, 0.7, and 7 for the three cases (Table 3), and the travel distance $D=U\Delta t$ is fixed at 20 cm.

The droplet-cantilever system can be modelled as a simple harmonic oscillator, and in the underdamped case (Fig. 4A–C), we expect significant ringing artefact described by the force response

Open Access Article. Published on 29 1446. Downloaded on 05/03/46 04:17:07.

$$F(t) = F_0 e^{-t/\tau} \cos(\omega_o t + \phi) + F_{\text{fric}} \quad \text{for } \frac{b}{\sqrt{4mk}} \ll 1$$
 (2)

with a decay/response time of $\tau=2m/b$, and where F_0 and the phase ϕ are fitting parameters that depend on initial conditions (See Supporting Fig. S3 for detailed derivation). The experimental force curve in Fig. 4C (blue circles) is well described by Equation 2 (blue line) with a fitted response time $\tau_{\rm fit}=0.62$ s that is in good agreement with the theoretical value of 2m/b=0.8 s (Table 3). Discrepancy between the two is likely due to uncertainty in b value.

In contrast, for a system close to critically damped (Fig. 4D–F), there is no ringing and F(t) has the form

$$F(t) = F_0 e^{-t/\tau} + F_{\text{fric}} \quad \text{for } \frac{b}{\sqrt{4mk}} \approx 1$$
 (3)

reaching the $F_{\rm fric}=1.9~\mu{\rm N}$ value with the fastest possible time $\tau=1/\omega_o$. The experimental force curve in Fig. 4F (blue circles) is again well fitted with Equation 3 (blue line), with $\tau_{\rm fit}=0.04~{\rm s}$ that is in excellent agreement with expected $1/\omega_o=0.037~{\rm s}$. The initial overshoot of the experimental data (with respect with theoretical predictions) is due to the fact that the system is slightly underdamped $b/\sqrt{4mk}=0.7$. Physically, critical damping is achieved when the droplet inertia is balanced by the viscous component: $mU\omega_o\sim bU$ and hence $b\sim \sqrt{mk}$.

For an overdamped system (Fig. 4G–I), the force response function has a similar form to the critically damped one

$$F(t) = F_0 e^{-t/\tau} + F_{\text{fric}} \quad \text{for } \frac{b}{\sqrt{4mk}} \gg 1$$
 (4)

except with a larger $\tau=b/k$. Fitting the experimental data in Fig. 4I (blue circles) with Equation 4 gives $\tau_{\rm fit}=0.3~{\rm s}\gg 1/\omega_o$ and in good agreement with the expected value of $b/k=0.5~{\rm s}$.

We obtained similar friction values for undamped and critically damped cantilevers: $F_{\rm fric}=1.7\pm0.2~\mu{\rm N}$ and $F_{\rm fric}=1.93\pm0.01~\mu{\rm N}$, respectively. In contrast, $F_{\rm fric}=1.50\pm0.01~\mu{\rm N}$ is significantly smaller with overly damped cantilever, likely because there is insufficient time for $F_{\rm fric}$ to reach its equilibrium value (Table 3). The advantages to using a critically damped cantilever are therefore clear. $F_{\rm fric}$ can be accurately measured with minimal ΔF , since ringing artefact can be avoided, and the cantilever responds with the fastest theoretical time possible.

3.3 Probing different origins of droplet friction on superhydrophobic surfaces

Using a critically damped cantilever, we are now able to measure $F_{\rm fric}$ over an unprecedented range of U from 10 $\mu \rm m~s^{-1}$ to 30 cm s⁻¹ without any Gibbs noise. We identified two regimes of droplet frictions at low and high speeds. At low $U < 1~{\rm cm~s^{-1}}$, $F_{\rm fric}$ is independent of U, and there is significant fluctuations $\Delta F = 0.2~\mu \rm N$ in the force curve (Inset in Fig. 5B). In contrast, at high $U > 10~{\rm cm~s^{-1}}$, $F_{\rm fric} \propto U^{2/3}$ increases with U, and the force curve exhibits ultra-low $\Delta F < 10~{\rm nN}$ (Inset in Fig. 5C).

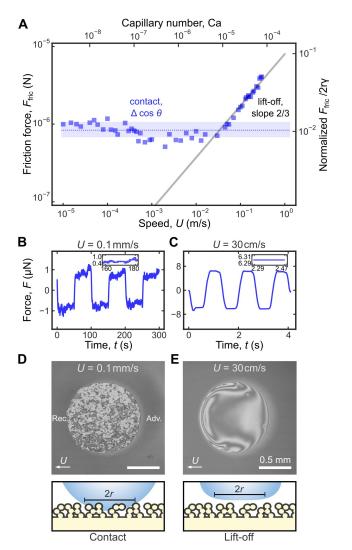

Fig. 5 Origins of droplet friction probed using a critically damped cantilever. (A) Friction force $F_{\rm fric}$ as a function of speed U. Secondary x and y axes are U and $F_{\rm fric}$ in their non-dimensional form. Droplet volume is 20 μ L. (B, C) The corresponding force curves for at low U=0.1 mm s⁻¹ and high U=30 cm s⁻¹. Droplet base visualized using Reflection Interference Contrast Microscopy. (D) At low U=0.1 mm s⁻¹, droplet is in contact with the topmost solid fractions. The advancing (Adv.) front and the receding (Rec.) ends are indicated on the image. (E) At high U=30 cm s⁻¹, the droplet lifts off the surface. Arrows indicate motion of the surface. Scale bars for D and E are 0.5 mm.

To explain the physical origins of the two regimes, we shone monochromatic light (wavelength $\lambda=561$ nm) from below to visualize the droplet base, i.e., Reflection Interference Contrast Microscopy (RICM). At low U=0.1 mm s $^{-1}$, a droplet is in contact with the topmost tips of the surface (Cassie-Baxter state). Roughness of the superhydrophobic surface results in variations in the air film thickness beneath the droplet, which manifest as bright and dark fringes due to interference effects (Fig. 5D). Between neighbouring bright and dark fringes, there is a difference in air-film thickness of $\sim \lambda/2$ or 200 nm (Supporting Fig. S4A).

In this regime, $F_{\rm fric}$ (and the observed $\Delta F_{\rm contact} = 0.2~\mu N$ in Fig. 5B) is attributed to contact-line pinning, resulting in discontinuous contact-line profile at the receding end (Supporting

Open Access Article. Published on 29 1446. Downloaded on 05/03/46 04:17:07.

Video 1). Furmidge's law predicts that $F_{\rm fric}$ is directly related to contact angle hysteresis, specifically that $F_{\rm fric}/2r\gamma = \Delta\cos\theta = \cos\theta_{\rm rec} - \cos\theta_{\rm adv}$, where r is droplet base radius and γ the surface tension.

On the other hand, at high speeds $U > 10~{\rm cm~s^{-1}}$, droplet motion can generate sufficient lift to balance its weight, and the the droplet completely lifts off the surface ^{28–30}. There is no contact-line pinning, and as a result, the droplet base profiles at both the advancing front and receding end are smooth and continuous (Fig. 5E, Supporting Fig. S4B and Videos 2–4), with the characteristic horseshoe shape as described in previous reports ³⁰. Contact angle measurements can no longer describe droplet friction in this limit, since there is no three-phase contact line. The lack of contact-line pinning due to droplet lift-off explains the ultralow $\Delta F = \Delta F_{\rm noise} < 10~{\rm nN}$ (Inset in Fig. 5C) in the force curve. Note that without damping, the force curve is dominated by Gibbs noise (Fig. 2C), and we will not be able to come to this conclusion.

Instead, friction is dominated by the viscous dissipation in the air layer whose thickness h increases with U. Following the classical analysis by Landau, Levich, and Derjaguin 22,23 , $h \propto R \, \mathrm{Ca}^{2/3}$, where $\mathrm{Ca} = \eta U/\gamma$ is the capillary number based on the air viscosity $\eta = 1.85 \times 10^{-5} \, \mathrm{Pa} \cdot \mathrm{s}$ and the surface tension of water $\gamma = 72 \, \mathrm{mN} \, \mathrm{m}^{-1}$. Viscous dissipation occurs largely in the perimeter of the droplet base of size $l \propto R \, \mathrm{Ca}^{1/3}$, and we expect $F_{\mathrm{fric}} \sim 2r l (\eta U/h)$ and hence $F_{\mathrm{fric}}/2r\gamma \sim \mathrm{Ca}^{2/3} \propto U^{2/3}$ (full line in Fig. 5A). Recently, Backholm $et \, al.$ (2024) reported a similar increase of F_{fric} with U on superhydrophobic surfaces and proposed that $F_{\mathrm{fric}} \propto U$; however, $F_{\mathrm{fric}} \propto U^{2/3}$ gives a better fit to their experimental data (Supporting Fig. S5).

4 Universal droplet friction laws for super-repellent

In Fig. 5, we only looked at friction for water droplets (viscosity $\eta_d=10^{-3}~{\rm Pa\cdot s}$) of a fixed volume $V=20~{\rm \mu L}$ on a Glaco superhydrophobic surface which has a porous texture consisting of nanoparticles (Fig. 6A). In Fig. 6, we additionally measured $F_{\rm fric}$ for a wider range of volumes V=15–30 ${\rm \mu L}$ not just for Glaco surface, but also for black silicon, a different superhydrophobic surface with needle-like structures. We have also included previously published friction data for silicone oil droplets (V=20–50 ${\rm \mu L}$ and of much higher viscosity $\eta_d=10^{-1}~{\rm Pa\cdot s}$) on underwater superoleophobic surface for comparison 14 . Unlike superhydrophobic surface, the underwater superoleophobic surface is smooth at the nanoscale and does not rely on texturing to achieve liquid-repellency (Fig. 6B); instead, the zwitterionic brushes on the surface generate electric double-layer forces which stabilize a water layer beneath the oil droplet.

The entire friction dataset in Fig. 6C spans a wide range of $F_{\rm fric}$ (close to 3 decades, from 20 nN to 6 μ N) and droplet speeds (over 4 decades, from 10 μ m s⁻¹ to 30 cm s⁻¹). The same data can be presented in their non-dimensionalized form $F_{\rm fric}/2r\gamma$ vs. Ca as shown in Fig. 6D (raw data in ³¹). For the zwitterionic surface, we use the water-oil interfacial tension $\gamma=50$ mN m⁻¹ and the water viscosity $\eta=10^{-3}$ Pa·s values to calculate Ca (c.f., water

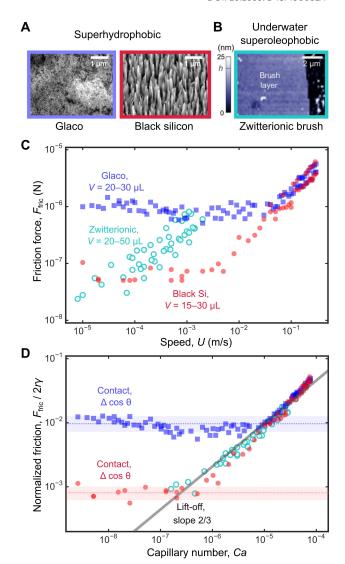

Fig. 6 Universal friction laws on different surfaces. (A) Scanning electron micrographs of Glaco and black silicon superhydrophobic surfaces. (B) Topography of the zwitterionic brush layer (in water) obtained using atomic force microscope. On the right, the brush layer has been scratched to reveal the underlying glass surface. (C) Friction forces measured for the three surfaces over a wide range of speeds from 10 $\mu m \ s^{-1}$ to 30 cm s⁻¹. (D) The same data in C non-dimensionalized as $F_{\rm fric}/2r\gamma$ vs. Ca. Data for zwitterionic brush surface is taken from our previous work 14 .

surface tension $\gamma=72$ mN m $^{-1}$ and air viscosity $\eta=1.8\times10^{-5}$ Pa·s for superhydrophobic surface). Parameters used to generate the non-dimensional plot is summarized in Table 4.

As discussed previously, there are two regimes of droplet friction, one dominated by contact-line pinning and another by viscous dissipation

$$F_{\text{fric}}/2r\gamma = \begin{cases} \Delta\cos\theta & \text{contact-line pinning} \\ 20\,\text{Ca}^{2/3} & \text{viscous dissipation} \end{cases} \tag{5}$$

. For Glaco surface, contact-line pinning dominates for $U<10~{\rm cm~s^{-1}}$ and Ca $<10^{-5}$ with constant $F_{\rm fric}/2r\gamma=(1.0\pm0.1)\times10^{-2}$ (blue band in Fig. 6D). For black silicon, pinning is dominant for smaller $U<1~{\rm cm~s^{-1}}$ and Ca $<10^{-6}$, with a lower $F_{\rm fric}/2r\gamma=1$

 $(8\pm2)\times10^{-4}$ (red band in Fig. 6D), reflecting its more water-repellent nature. It is difficult to directly compare friction and contact angle measurements to confirm Furmidge's law, because of large measurement error for $\theta>170^\circ$ (See discussion in 'Contact angle measurements' subsection in 'Materials and Methods'). Previously, we showed that for an oil droplet moving on zwitterionic brush surface, the droplet is never in contact with the solid and contact-line pinning is always absent. Hence, there is no constant $F_{\rm fric}/2r\gamma$ regime.

Above critical speeds corresponding to Ca = 10^{-5} and 10^{-6} for Glaco and black silicon, the water droplet lifts off the surface and viscous dissipation in the air layer dominates with $F_{\rm fric}/2r\gamma=20$ Ca^{2/3} (full line in Fig. 6D, prefactor of 20 obtained by least square fit to data) independent of the surface structure. There is excellent overlap between friction data for oil droplets on zwitterionic surface and for water on superhydrophobic surfaces, even though the droplet viscosities are very different (η_d is 100 times larger for oil than for water), i.e., dissipation due to internal flow of droplet is insignificant. Instead, $F_{\rm fric}$ on zwitteronic surface is always dominated by viscous dissipation in the *water* layer beneath the oil droplet, due to the same LLD droplet lift-off mechanism.

The scaling law in Equation 5 is therefore universal, and the Ca^{2/3} scaling applies equally to superhydrophobic and underwater superoleophobic surface, despite their very different surface topographies and chemistries. At even higher speeds \sim m s⁻¹, other dissipation mechanisms, such as aerodynamic drag can become important ³². However, since droplet speeds here $U \leq 30$ cm s⁻¹ are relatively low, the drag force $F_{\rm drag} \sim \rho_a R^2 U^2/{\rm Re}^{1/2} \sim 20$ nN is small and therefore unimportant. Re = $\rho_a U R/\eta < 30$ is the Reynolds number, ρ_a and η are the air density and viscosity, and R is the droplet radius.

Conclusions

To conclude, we have proposed a design for a critically damped cantilever which allows us measure droplet frictions accurately at high speeds without any ringing artefacts. We are able to then identify a new droplet friction regime on superhydrophobic surfaces where $F_{\rm fric}/2r\gamma\sim {\rm Ca}^{2/3}$ at high speeds. We further showed that this scaling is universal and remains true for both superhydrophobic and underwater superoleophobic surface, irrespective of the details of surface structure and chemistry.

Author contributions

S.A. performed the bulk of the experiments. D.D. and M.L. came up with the design of the critically damped cantilever, analyzed the results, and wrote the manuscript. D.D. conceptualized the

project and supervised the research.
