# Oxygen vacancies induced low overpotentials of Ag/CeO<sub>2</sub> for electrocatalytic evolution of oxygen and hydrogen†

Ajit Kumar Dhanka,<sup>a</sup> Mayank Tiwari,<sup>b</sup> Prashant Kumar Bhartiya,<sup>c</sup> Balaram Pani,<sup>d</sup> Nityananda Agasti<sup>\*a</sup> and Debabrata Mishra<sup>\*b</sup>

Designing efficient catalysts for the evolution of hydrogen and oxygen through electrocatalytic water splitting remains an area of significant interest. Herein, we develop an Ag/CeO<sub>2</sub> catalyst that demonstrates a remarkable electrocatalytic performance for hydrogen and oxygen evolution through water splitting. The high catalytic activity can be attributed to the interaction between Ag and CeO<sub>2</sub>, which increases the oxygen vacancies at the interface. This is substantiated by the results from Raman, X-ray photoelectron, electron paramagnetic resonance and photoluminescence spectroscopy. The reduced photoluminescence intensity validates the effective separation of photogenerated electron–hole pairs due to oxygen vacancies. Besides increasing the oxygen vacancies, Ag enhances light absorption and reduces the band gap of CeO<sub>2</sub>, which is evident from a remarkable enhancement in the electrocatalytic activity of Ag/CeO<sub>2</sub>, especially under light illumination, compared to pristine CeO<sub>2</sub>. Notably, a drastic reduction in overpotential and an increase in current density are observed for Ag/CeO<sub>2</sub>. For the oxygen evolution reaction, Ag/CeO<sub>2</sub> exhibits a reduction of 120 mV in the overpotential and an increase of 19.8 mA cm<sup>-2</sup> in the current density with the lowest Tafel slope of 158 mV dec<sup>-1</sup> compared to CeO<sub>2</sub>. For the hydrogen evolution reaction, Ag/CeO<sub>2</sub> exhibits a reduction of 130 mV in the overpotential and an increase of 14.1 mA cm<sup>-2</sup> in the current density. Considering the results from characterization techniques and electrocatalytic experiments, a plausible mechanism has been proposed for the electrocatalytic performance of the catalyst. This study offers insights into defect-induced ceria-based materials for optimizing and designing effective electrocatalysts for overall water splitting.

## 1. Introduction

Fossil fuels such as coal, natural gas, and crude oil are essential for meeting energy demands and are used to power various aspects of daily life, agriculture, transportation, and industry. However, the excessive consumption of fossil fuels, due to the combination of rapid economic expansion and an increasing global population, presents a significant threat of future

shortages.<sup>1</sup> Researchers have predicted that the crude oil may be depleted in 40–50 years,<sup>2</sup> coal production will peak by 2042–2062,<sup>3</sup> and demand for clean energy is projected to rise 50% by 2030.<sup>4</sup> To address these challenges, hydrogen emerges as a viable solution, offering a clean, efficient energy alternative with high energy density and zero carbon emissions.<sup>5,6</sup> Steam reforming is a cost-effective way to produce hydrogen; however, it has environmental limitations.<sup>7</sup> In contrast, electrochemical water splitting offers a cleaner and more sustainable method for generating hydrogen. Electrochemical water splitting consists of the hydrogen evolution reaction (HER) to produce hydrogen and the oxygen evolution reaction (OER) to generate oxygen.<sup>8</sup> High overpotentials, sluggish reaction kinetics, catalyst stability, and the requirement for scalable, inexpensive materials are some of the challenges faced by HER and OER electrocatalysts.<sup>9,10</sup> Electrocatalytic water splitting using semiconductor metal oxides as catalysts has gained significant interest.<sup>11,12</sup> Oxides of rare earth metals, especially cerium (Ce), have been widely used as catalysts due to their flexible interconversion of the oxidation state (Ce<sup>4+</sup> ↔ Ce<sup>3+</sup>). The conversion

between  $\text{Ce}^{4+}$  and  $\text{Ce}^{3+}$  results in the formation of oxygen vacancies in the lattice structure denoted as  $\text{Ce}^{4+}\text{-O}_v\text{-Ce}^{3+}$  (where  $\text{O}_v$  represents an oxygen vacancy), an inherent property of  $\text{CeO}_2$  that makes it a potential redox material for electrocatalytic oxygen evolution reactions (OER).<sup>13,14</sup> Moreover,  $\text{CeO}_2$ , being an n-type semiconductor with a band gap of 3.2 eV, acts as a good photocatalyst.<sup>15</sup> Its remarkable redox behavior and suitable band gap make it a potential candidate for photoelectrocatalysis. However, there are limitations with ceria due to its wide band gap. Therefore, it is of great importance to develop highly efficient ceria nanostructures for photoelectrocatalytic applications.

Recently, the development of ceria-based nanomaterials by modulating the band gap and increasing defects on the ceria surface has been demonstrated as an effective strategy to improve the light-harvesting capability and restrain electron-hole recombination for enhanced photoelectrocatalytic performance.<sup>16–18</sup> For example, Ghosh *et al.* have reported a ceria-based heterojunction catalyst for hydrogen evolution, where the band gap and defects in ceria contributed to enhanced photoelectrocatalytic activity.<sup>19</sup> Although efforts were made to prepare ceria-based materials, reports on in-depth characterization of defects in ceria and the mechanistic details highlighting the role of defects in the catalytic performance of the material are limited.<sup>20–23</sup> Hence, this work offers a detailed study revealing structural characterization of defects in ceria-based materials and a mechanistic study of the roles of defects in catalytic activity. Besides having good catalytic properties, ceria also acts as a good catalyst support, onto which metal or metal oxide nanoparticles can be incorporated to produce heterojunctions. The introduction of metal nanoparticles onto the surface of a ceria support forms metal-ceria junctions, which can result in a synergistic effect and facilitate interfacial charge transfer, thereby improving photoelectrocatalytic performance. Furthermore, the metal nanoparticles can act as photosensitizers to strengthen the light absorption of the metal-ceria composite. Additionally, the strong metal-support interaction between metal nanoparticles and ceria increases defects on the surface of ceria and reduces the band gap in ceria.

Considering the importance of developing high-performance electrocatalysts based on ceria-based materials, in this report we describe  $\text{Ag/CeO}_2$  prepared by a solvothermal method, as an effective catalyst for oxygen and hydrogen evolution by electrocatalytic water splitting. The electrocatalytic performance of  $\text{Ag/CeO}_2$  as a catalyst is found to be distinctly higher than that of pristine  $\text{CeO}_2$  for electrocatalytic water splitting. The activity of  $\text{Ag/CeO}_2$  was enhanced remarkably under light illumination.  $\text{Ag/CeO}_2$  exhibited a 120 mV reduction in the overpotential and a  $19.8 \text{ mA cm}^{-2}$  increase in the current density compared to  $\text{CeO}_2$  for the oxygen evolution reaction. For the hydrogen evolution reaction,  $\text{Ag/CeO}_2$  exhibited superior activity to  $\text{CeO}_2$  with an overpotential reduction of 130 mV and a  $14.1 \text{ mA cm}^{-2}$  enhancement in the current density. The materials characterization results confirm the role of Ag and  $\text{Ag/CeO}_2$  (metal-support) interactions in achieving enhanced electrocatalytic performance. Ag nanoparticles improve light absorption and enhance the

absorption intensity through the localized surface plasmon resonance (LSPR) effect at the  $\text{Ag/CeO}_2$  interface. The incorporation of Ag also reduces the band gap of  $\text{CeO}_2$  to 2.90 eV. Moreover, due to the strong metal-support interaction between Ag and  $\text{CeO}_2$ , there is an increase in surface oxygen vacancies on  $\text{CeO}_2$ . The surface oxygen vacancies trap the photogenerated electrons causing delayed recombination of photogenerated electron and hole pairs. Overall, the interaction between Ag and  $\text{CeO}_2$  improves the optical properties, reduces the band gap, enhances the charge carrier separation, and restrains the recombination of photogenerated carriers, thereby resulting in an improvement in the overall water splitting process. A plausible mechanism was also proposed to understand the role of the  $\text{Ag/CeO}_2$  catalyst in electrocatalytic water splitting for hydrogen and oxygen evolution reactions.

## 2. Experimental section

### 2.1 Materials

Cerium nitrate hexahydrate (99%) ( $\text{Ce}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ ) and sodium hydroxide (98%) ( $\text{NaOH}$ ) were obtained from CDH India; silver nitrate ( $\text{AgNO}_3$ , 98.5%) from Merck; and ethanol ( $\text{C}_2\text{H}_5\text{OH}$ ) and methanol ( $\text{CH}_3\text{OH}$ ) from Sigma-Aldrich, India. Deionized (DI) water was used in the experiments. All chemicals used were of analytical grade and directly used as received without further purification.  $\text{Ag/CeO}_2$  nanocomposites were synthesized following the literature method.<sup>24</sup>

### 2.2 Preparation of $\text{Ag/CeO}_2$

The  $\text{Ag/CeO}_2$  nanocomposites were prepared *via* a solvothermal method<sup>24,25</sup> (Scheme 1). In a typical synthesis procedure, a 1 : 10 weight ratio of  $\text{AgNO}_3$  to  $\text{Ce}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ , corresponding to a molar ratio of  $\text{AgNO}_3$  (0.59 mmol) to  $\text{Ce}(\text{NO}_3)_3$  (2.4 mmol), was used. Firstly, 0.1 g of  $\text{AgNO}_3$  and 1.0 g of  $\text{Ce}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$  were dissolved in 50 mL of methanol, followed by the addition of 0.25 g (6.25 mmol) of sodium hydroxide under magnetic stirring for 30 minutes to create a homogenous solution. Furthermore, the resultant reaction mixture was transferred to a 100 ml Teflon-lined stainless-steel autoclave and sealed. Then, the autoclave was heated at  $180 \text{ }^\circ\text{C}$  and maintained at this temperature for 18 hours. The autoclave was left to cool naturally to room temperature. The formed precipitate was collected and washed three to four times with ethanol by centrifugation at 3000 rpm for 10 minutes to remove any residual chemicals from the precipitate. Afterward, the precipitate was heated in an oven at  $80 \text{ }^\circ\text{C}$  for 4 hours and subsequently calcined at  $250 \text{ }^\circ\text{C}$  for 2 hours, yielding a grey color powder of  $\text{Ag/CeO}_2$  nanocomposites. For comparison,  $\text{CeO}_2$  nanoparticles were synthesized using a similar procedure but without the addition of  $\text{AgNO}_3$ . No additional reducing agent was used in the preparation of materials. In the presence of  $\text{NaOH}$ ,  $\text{Ce}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$  precipitates into  $\text{Ce}(\text{OH})_3$ , which under hydrothermal conditions converts into  $\text{CeO}_2$ .  $\text{AgNO}_3$  in the presence of  $\text{NaOH}$  forms  $\text{Ag}_2\text{O}$  as an intermediate to form Ag

Scheme 1 Preparation of Ag/CeO<sub>2</sub> nanocomposites by a solvothermal method and their application in water splitting.

nanoparticles. NaOH facilitates the nucleation of Ag nanoparticles.<sup>26</sup>

### 2.3 Fabrication of electrodes for electrochemical measurements

The electrodes were fabricated by drop-casting the prepared CeO<sub>2</sub> and Ag/CeO<sub>2</sub> on nickel foam (NiF). The first electrode was fabricated by drop-casting CeO<sub>2</sub> as the active material, polyvinylidene fluoride (PVDF) as the binder, and carbon black as the conducting agent. The ratio of these components was 75:15:10, respectively. Similarly, the second electrode was prepared by drop-casting Ag/CeO<sub>2</sub> as the active material, PVDF as the binder, and carbon black as the conducting agent in the same ratio. These composites were applied onto a nickel foam using the drop-casting method, covering an area of 1 cm<sup>2</sup>. Following the application of the coating, the electrodes were placed in a vacuum oven at a temperature of 80 °C for 10 hours to facilitate drying. Subsequently, the electrodes were allowed to cool down naturally until they reached room temperature. The fabricated electrodes were named NiF, NiF/CeO<sub>2</sub>, and NiF/Ag/CeO<sub>2</sub>. NiF/CeO<sub>2</sub>/Light and NiF/Ag/CeO<sub>2</sub>/Light have been abbreviated to the electrocatalytic activity of NiF/CeO<sub>2</sub> and NiF/Ag/CeO<sub>2</sub> under light illumination.

### 2.4 Electrochemical measurements

Electrochemical measurements including linear sweep voltammetry (LSV), electrochemical impedance spectroscopy (EIS), and chronoamperometry were conducted in an alkaline environment using a computerized potentiostat/galvanostat (CS350 Corr-Test electrochemical workstation) within a standard three-electrode electrochemical setup. The counter electrode used was platinum (Pt) and Ag/AgCl was utilized as the reference electrode. The potential values were converted to the reversible hydrogen electrode ( $E_{\text{RHE}}$ ) scale using the Nernst equation.<sup>27</sup> All the electrochemical experiments were conducted using a 1 M KOH solution as the electrolyte. The visible light source emitting a wavelength of  $\lambda = 405$  nm was utilized

for illumination during the electrochemical experiments, which was positioned 5 cm away from the working electrode.

### 2.5 Materials characterization

The microstructural and morphological features of the synthesized materials were characterized by multiple techniques. Powder X-ray diffraction (PXRD) was conducted to study the crystalline patterns of the materials using a diffractometer with Cu K radiation ( $\lambda = 0.1542$  nm) in the  $2\theta$  range of 10–80. To study the optical properties of the materials, UV-visible spectra were obtained using a Shimadzu 1800 spectrometer and UV-vis diffuse reflectance spectra (DRS) were obtained using an Agilent Cary 5000. Raman spectroscopy study was carried out using a laser Raman spectrometer, model: inVia II. Field emission scanning electron microscopy (FESEM) using an Oxford-EDX system IE 250 X Max 80 (FEI Quanta 200 F SEM) at a high-resolution with a thermally aided field emission gun (FEG) at an acceleration voltage of  $U_{\text{acc}} = 0.2\text{--}30$  kV was conducted to study the morphology and elemental composition of the materials. High-resolution transmission electron microscopy (HRTEM) images of the materials were collected using a TECNAI G20 HR-TEM 200 kV. To assess the surface area and pore characteristics of the synthesized materials, nitrogen adsorption-desorption measurements were carried out using the Autosorb-iQ XR system from Quantachrome Instruments. Prior to analysis, the samples were degassed at 150 °C for 10 hours under a high vacuum of approximately  $1 \times 10^{-2}$  bar to remove any adsorbed impurities. The isotherms were subsequently recorded at 77 K, employing a liquid nitrogen environment to ensure accurate measurements. X-ray photoelectron spectroscopy (XPS) was performed using a Kratos Axis Supra Plus XPS equipped with a monochromatic Al K $\alpha$  X-ray source (1486.6 eV). The high-resolution data were calibrated using the C 1s peak at a binding energy of 284.5 eV as the standard. The photoluminescence (PL) study was performed at normal temperature on a Horiba Yvon PTI QuantaMaster (8450-11) spectrophotometer with a 375 nm nano-LED as the excitation source. The charge carrier lifetimes were

determined by employing time-resolved photoluminescence (TRPL) measurements (in micro- and milliseconds) using a 980 nm laser and a xenon lamp as light sources in modulated mode.

### 3. Results and discussion

#### 3.1 Structure, morphology, and elemental analysis

To understand the formation of the Ag/CeO<sub>2</sub> nanocomposite, the optical properties were analyzed by UV-visible spectroscopy and compared with those of pristine CeO<sub>2</sub>. The absorption bands at wavelengths of 340 nm and 327 nm in the UV-visible absorption spectra (Fig. S1, ESI<sup>†</sup>) correspond to Ag/CeO<sub>2</sub> and CeO<sub>2</sub>, respectively.<sup>28</sup> The absorption band corresponding to Ag/CeO<sub>2</sub> suffers a red shift compared to CeO<sub>2</sub>. The red shift in the absorption band can be attributed to a decrease in the band gap of Ag/CeO<sub>2</sub> because of the addition of Ag, suggesting the formation of the composite material.<sup>29</sup> To calculate the direct band gap energy ( $E_g$ ) of Ag/CeO<sub>2</sub>, UV-vis diffuse reflectance spectra (DRS) were recorded. To mitigate the influence of scattered light, the DRS spectra were transformed using the Kubelka–Munk (K–M) function. The plot of the K–M function versus the energy of light is shown in Fig. S2 (ESI<sup>†</sup>). From this plot, the band gap energies for Ag/CeO<sub>2</sub> were derived. The intercept on the abscissa axis of a linear fit of the Kubelka–Munk function  $\alpha hv = A(h\nu - E_g)^{n/2}$  corresponds to the  $E_g$  values, where  $E_g$ ,  $\alpha$ ,  $A$ ,  $h$ , and  $\nu$  represent the band gap, absorption coefficient, a constant, Planck's constant, and light frequency, respectively.<sup>30</sup> The DRS spectra reveal band gap energies of 3.25 eV for CeO<sub>2</sub> and 2.90 eV for Ag/CeO<sub>2</sub>, which represent the

energy gap between the valence band and conduction band. The reduction in band gap and the shift of the absorption band to a longer wavelength in Ag/CeO<sub>2</sub> are attributed to the incorporation of Ag into CeO<sub>2</sub> because the addition of Ag facilitates the excitation of electrons from the conduction band to the valence band within the CeO<sub>2</sub> lattice.<sup>31</sup> The formation of Ag/CeO<sub>2</sub> was confirmed by XRD analysis in the  $2\theta$  range of 10–80°. The XRD pattern (Fig. 1a) for pristine CeO<sub>2</sub> exhibited peaks at  $2\theta$  angles of 28.4°, 32.9°, 47.5°, 56.3°, 59.0°, 69.3°, 76.7°, and 78.8°, corresponding to the (111), (200), (220), (311), (222), (400), (331), and (420) planes, respectively. These peaks are indicative of a cubic fluorite structure, consistent with the JCPDS File No. 34-0394.<sup>32</sup> Compared to pristine CeO<sub>2</sub>, the XRD pattern of Ag/CeO<sub>2</sub> exhibits additional peaks at 38.5°, 47.7°, 64.9°, and 76.7° corresponding to the (111), (200), (220), and (311) planes of cubic Ag (peaks presented with asterisks)<sup>33,34</sup> (JCPDS No. 04-0783). The appearance of these peaks confirms the successful incorporation of Ag into CeO<sub>2</sub>. This incorporation is further supported by a shift in diffraction peaks to higher angles in Ag/CeO<sub>2</sub> compared to pristine CeO<sub>2</sub>, as shown in Fig. S3 (ESI<sup>†</sup>). This shift is most noticeable in the prominent (111) diffraction peak of Ag/CeO<sub>2</sub>.<sup>35,36</sup> Additionally, in the diffraction pattern of Ag/CeO<sub>2</sub>, there is a decrease in the intensity and broadening (Fig. S3, ESI<sup>†</sup>) of all diffraction peaks corresponding to CeO<sub>2</sub>, suggesting defect generation in CeO<sub>2</sub> due to Ag addition.<sup>37</sup> The broadening of peaks can be attributed to the reduction in the crystallite size of CeO<sub>2</sub>. The average crystallite size, calculated using the Scherrer equation<sup>38</sup> ( $D = K\lambda/\beta \cos \theta$  with  $K = 0.98$ ,  $\lambda = 1.54 \text{ \AA}$ , and  $\beta$  being the full width at half maximum (FWHM) of the (111) peak), was found to be approximately 7 nm for CeO<sub>2</sub> and 6 nm for Ag/CeO<sub>2</sub>.

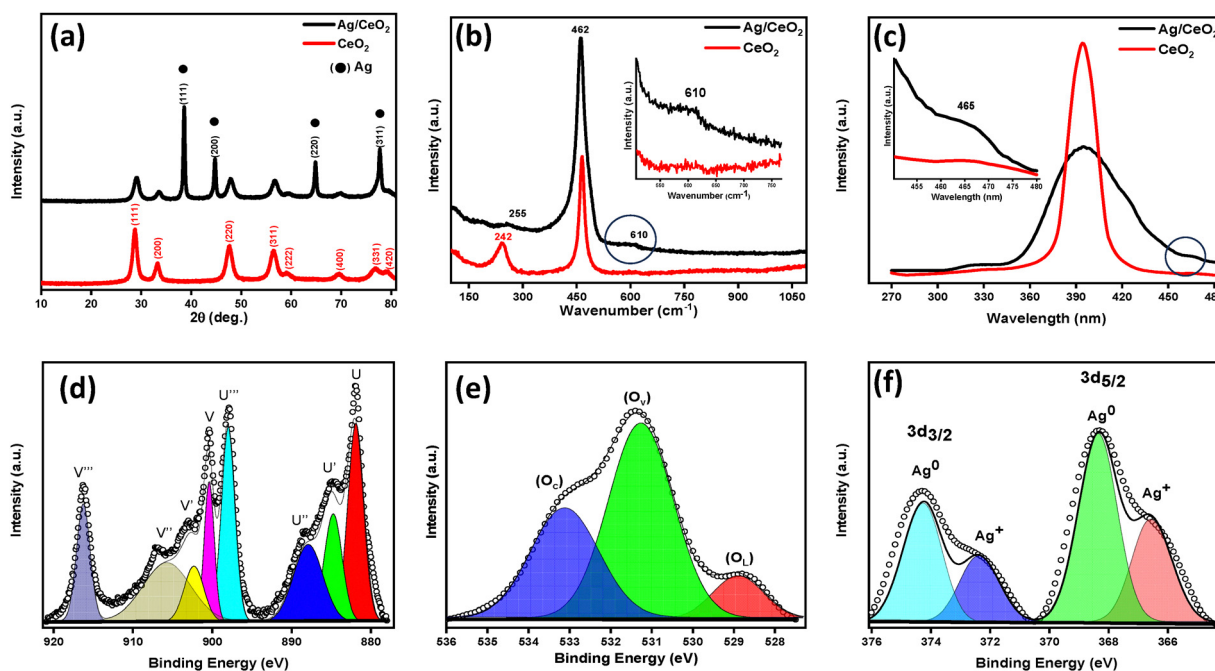

Fig. 1 (a) XRD patterns, (b) Raman spectra, and (c) PL spectra of CeO<sub>2</sub> and Ag/CeO<sub>2</sub> nanocomposites and the XPS spectra and (d) deconvoluted spectra of Ce 3d, (e) O 1s, and (f) Ag 3d for Ag/CeO<sub>2</sub> nanocomposites.

To further support the formation of Ag/CeO<sub>2</sub> nanocomposites and confirm the formation of defects (oxygen vacancies) on the surface of ceria, Raman spectra were recorded in the range of 100–1100 cm<sup>-1</sup> (Fig. 1b). The prominent peak at 465 cm<sup>-1</sup> in the spectra corresponds to the F<sub>2g</sub> mode originating from the symmetric stretching of the Ce–O bond.<sup>39,40</sup> Compared to pristine CeO<sub>2</sub>, the Ag/CeO<sub>2</sub> composites exhibited a shift towards a lower wave number in the F<sub>2g</sub> stretching mode, with a peak at 462 cm<sup>-1</sup> (Fig. S4a, ESI†). This downshift is due to an increase in oxygen vacancies induced by the incorporation of Ag<sup>41</sup> because oxygen vacancies disrupt the Ce–O vibrational unit leading to the downshift of the F<sub>2g</sub> mode. In the Ag/CeO<sub>2</sub> composite, additional peaks appearing with distinct intensities at 255 and 610 cm<sup>-1</sup> correspond to the F<sub>1u</sub> symmetric mode<sup>42</sup> and the defect-induced mode (*D*) due to intrinsic oxygen vacancies.<sup>43</sup> The band at 610 cm<sup>-1</sup>, which is not present in pristine CeO<sub>2</sub>, shows an increase in oxygen vacancies in Ag/CeO<sub>2</sub>. An increase in oxygen vacancies in Ag/CeO<sub>2</sub> is also inferred from the expansion in the FWHM of the F<sub>2g</sub> peak compared to that of pristine CeO<sub>2</sub><sup>41</sup> (Fig. 1d and Fig. S4a, ESI†). The increase in oxygen vacancies has been calculated from the ratio of the integrated area of the *D* peak to the F<sub>2g</sub> peak ( $I_D/I_{F_{2g}}$ ), which is a key parameter for measuring the relative concentration of oxygen vacancies on the surfaces of CeO<sub>2</sub> and Ag/CeO<sub>2</sub>. The Ag/CeO<sub>2</sub> catalyst demonstrates a higher  $I_D/I_{F_{2g}}$  ratio compared to pristine CeO<sub>2</sub>, suggesting higher oxygen vacancies in Ag/CeO<sub>2</sub> (Fig. S4b, ESI†). Additionally, the incorporation of Ag in the composite is further confirmed by the enhanced the F<sub>2g</sub> peak intensity, which arises from the strong optical absorption associated to the surface enhanced Raman scattering (SERS) effect.<sup>44,45</sup>

Furthermore, Ag/CeO<sub>2</sub> has been studied by photoluminescence (PL) analysis, which is a technique to ascertain oxygen vacancies and the efficiency of charge carrier trapping in semiconductor materials.<sup>46</sup> In this study, PL analysis was utilized to investigate the impact of oxygen vacancies on the separation of photogenerated electron–hole pairs in Ag/CeO<sub>2</sub> nanocomposites. In the PL spectra, CeO<sub>2</sub> emissions are often attributed to 4f → VB (valence band) transitions, which are strongly influenced by defects like oxygen vacancies in the material.<sup>47</sup> The PL spectra of CeO<sub>2</sub> and Ag/CeO<sub>2</sub> nanocomposites, shown in Fig. 1c, cover the range from 270 to 480 nm. For CeO<sub>2</sub>, a prominent UV emission peak at 394 nm is observed, corresponding to electron transition from the Ce 4f level to the O 2p level.<sup>48</sup> However, with the introduction of Ag, the intensity of this peak decreased substantially along with an additional emission band appearing at 465 nm. The band at 465 nm is mostly associated with the oxygen vacancies with trapped electrons.<sup>49</sup> The reduced photoluminescence intensity in Ag/CeO<sub>2</sub> suggests improved separation of electron–hole pairs due to the presence of oxygen vacancies, highlighting their role in enhancing charge carrier dynamics and overall material performance. This observation aligns well with the findings reported in previous studies.<sup>50</sup>

To further evaluate the formation of oxygen vacancies, oxidation states of Ce, and elemental composition, Ag/CeO<sub>2</sub> was

analyzed by X-ray photoelectron spectroscopy (XPS). The XPS spectra of CeO<sub>2</sub> and Ag/CeO<sub>2</sub> were carefully compared to understand the effect of Ag on CeO<sub>2</sub> in the Ag/CeO<sub>2</sub> nanocomposite. The XPS survey spectra (Fig. S5, ESI†) demonstrate the presence of Ce, O and Ag with peaks in the binding energy ranges of 877–922 eV (Ce 3d), 527–536 eV (O 1s), and 364.5–376.1 eV (Ag 3d). The positions of the photoelectron peaks for all the elements are corrected according to the standard carbon (C 1s) peak, which is set at 284.4 eV.

To analyze the oxidation states of cerium in Ag/CeO<sub>2</sub>, the high-resolution XPS spectra for Ce 3d were deconvoluted over the binding energy range of 877 to 922 eV (Fig. 1d). The XPS spectra of Ce 3d can be fitted according to eight characteristic peaks located at U (881.9 eV), U' (884.7 eV), U'' (887.9 eV), U''' (897.9 eV), V (900.3 eV), V' (902.3 eV), V'' (905.6 eV), and V''' (916.2 eV). The peaks U' and V' were identified for Ce<sup>3+</sup>, which are assigned to the oxygen vacancies, and the rest of the peaks V''', V'', V, U''', U'', and U correspond to Ce<sup>4+</sup>.<sup>51</sup> These peaks indicate the presence of both Ce<sup>3+</sup> and Ce<sup>4+</sup> electronic states on the surface of CeO<sub>2</sub>. Typically, Ce<sup>4+</sup> is the predominant valence state on the surface of ceria, with a smaller proportion of Ce<sup>3+</sup>. The presence of Ce<sup>3+</sup> alongside Ce<sup>4+</sup> points to oxygen vacancies within the CeO<sub>2</sub> crystals due to their interconversion.<sup>52</sup>

The surface concentration of Ce<sup>3+</sup> in Ag/CeO<sub>2</sub> can be determined by calculating the peak integral areas of Ce<sup>3+</sup> and Ce<sup>4+</sup> using the following formula:<sup>43</sup>

$$[\text{Ce}^{3+}] = \frac{(\text{Ce}^{3+})\text{Area}}{\sum (\text{Ce}^{4+} + \text{Ce}^{3+})\text{Area}} \times 100$$

The Ce<sup>3+</sup> content was found to be 17.89% in Ag/CeO<sub>2</sub> and 13.92% in CeO<sub>2</sub> (Table S1 and Fig. S6, ESI†). The higher Ce<sup>3+</sup> content in Ag/CeO<sub>2</sub> compared to pristine CeO<sub>2</sub> is due to interfacial charge transfer induced by the metal–support interaction between Ag and CeO<sub>2</sub>. Moreover, the Ce 3d peaks in Ag/CeO<sub>2</sub> are shifted towards high binding energies compared to pristine CeO<sub>2</sub>, which might be a consequence of the interfacial electron transfer from Ag to CeO<sub>2</sub> due to the strong interaction between Ag and CeO<sub>2</sub>.<sup>53,54</sup> The Ag/CeO<sub>2</sub> interface becomes oxygen vacancy-rich due to this interaction. Additionally, the presence of oxygen vacancies on the surface can be revealed from the XPS spectra for O 1s within the binding energy range of 527 to 536 eV (Fig. 1e). In the deconvoluted XPS spectra for O 1s, the peaks observed at 528.8 eV (O<sub>L</sub>), 531.3 eV (O<sub>V</sub>), and 533.1 eV (O<sub>C</sub>) in Ag/CeO<sub>2</sub> correspond to lattice oxygen (Ce<sup>4+</sup>–O<sup>2-</sup>), oxygen vacancies (Ce<sup>3+</sup>–O<sup>2-</sup>), and surface chemisorbed hydroxyl groups (–OH), respectively. The peak at 531.3 eV is ascribed to oxygen vacancies.<sup>41</sup> The presence of Ag is also confirmed by the Ag 3d peaks in the XPS spectra (Fig. 1f). The peaks at 368.2 eV and 374.2 eV, attributed to Ag 3d<sub>5/2</sub> and Ag 3d<sub>3/2</sub>, respectively, suggest the presence of metallic silver in Ag/CeO<sub>2</sub>. Further analysis of these peaks reveals additional peaks at 366.5 eV and 372.3 eV, which are indicative of Ag<sup>+</sup>. In a nutshell, the above results confirm the formation of the Ag/CeO<sub>2</sub> nanocomposite and also reveal the oxidation states of

Fig. 2 (a) EPR profiles measured (inset: the calculated  $g$  factor value) at room temperature and (b) BET analysis for  $\text{CeO}_2$  and  $\text{Ag/CeO}_2$  nanocomposites.

Ce, the effect of Ag on  $\text{CeO}_2$ , the interaction between Ag and  $\text{CeO}_2$ , and oxygen vacancies at the  $\text{Ag/CeO}_2$  interface.

The increased oxygen vacancies in  $\text{Ag/CeO}_2$  were further validated through electron paramagnetic resonance (EPR) analysis performed at room temperature for both pristine  $\text{CeO}_2$  and  $\text{Ag/CeO}_2$  samples (Fig. 2a). Compared to pristine  $\text{CeO}_2$ ,  $\text{Ag/CeO}_2$  exhibited more pronounced EPR signals, indicating a higher concentration of oxygen vacancies in the composite. The EPR spectra of  $\text{Ag/CeO}_2$  revealed distinct  $g$  values at 1.93, 1.99, and 2.21, which are characteristic of  $\text{Ce}^{3+}$  ions, thereby confirming the presence of oxygen vacancies. Additionally, signals with  $g$  values of 2.07 and 2.15 were associated with  $\text{O}_2^-$  species and  $\text{Ce}^{3+}-\text{O}^- - \text{Ce}^{4+}$  defect sites.<sup>55</sup> Collectively, the findings from PXRD, Raman spectroscopy, XPS, and EPR analyses corroborate the enhancement of oxygen vacancies in  $\text{Ag/CeO}_2$  compared to pristine  $\text{CeO}_2$ . This increase in oxygen vacancies is pivotal for the improved electrocatalytic performance of the  $\text{Ag/CeO}_2$  composite.

The surface morphology, elemental mapping, and elemental composition of  $\text{Ag/CeO}_2$  were characterized by field emission scanning electron microscopy (FESEM) analysis with energy dispersive X-ray analysis (EDX). The FESEM image (Fig. 3a) reveals the spherical shapes of  $\text{Ag/CeO}_2$ , while the mapping and EDX (Fig. 3b and c) spectrum verify the presence of Ag, Ce, and O with their elemental distributions being 40.44%, 45.68% and 13.89%, respectively.

Furthermore, high-resolution transmission electron microscopy (HRTEM) was employed to investigate the nanostructure of  $\text{Ag/CeO}_2$  (Fig. 4a and Fig. S7, ESI<sup>†</sup>). HRTEM analysis demonstrates Ag nanoparticles deposited onto the  $\text{CeO}_2$  surface. The HRTEM image (Fig. 4b) shows Ag (200) and  $\text{CeO}_2$  (111) planes with interplanar spacings of 0.205 nm and 0.312 nm, respectively. The corresponding selected area electron diffraction (SAED) patterns (Fig. 4c) reveal the polycrystalline nature of  $\text{Ag/CeO}_2$  with resolved lattice fringes indexed to (111), (220), (200), (222), (311), and (420) lattice planes closely matching those obtained from the XRD pattern of  $\text{Ag/CeO}_2$  nanocomposites. HRTEM images (Fig. S7, ESI<sup>†</sup>) reveal that Ag nanoparticles of

4–6 nm size are deposited on  $\text{CeO}_2$  particles sized 5–8 nm. The particle sizes are consistent with the crystallite sizes calculated using the Scherrer equation from the XRD pattern. Noticeably, Ag and  $\text{CeO}_2$  are in contact with each other, thereby causing defects at the interface. The existence of an interface is crucial as it promotes the increase in surface oxygen vacancies in  $\text{CeO}_2$  that can enhance catalysis.

Besides the nanostructure, the specific surface area, pore diameter, and pore volume of the  $\text{Ag/CeO}_2$  catalyst have significant effects on its catalytic activities. Therefore, the Brunauer–Emmett–Teller (BET) analysis based on the nitrogen ( $\text{N}_2$ ) adsorption–desorption experiment was conducted. The  $\text{N}_2$  adsorption–desorption isotherms (Fig. 2b) show a typical type-IV curve with a fast increase at higher relative pressures ( $p/p^\circ$ ), indicating the porous structure of the materials.<sup>41</sup> For pristine  $\text{CeO}_2$ , the BET-specific surface area, total pore volume, and average pore diameter were measured to be  $15.88 \text{ m}^2 \text{ g}^{-1}$ ,  $0.068 \text{ cm}^3 \text{ g}^{-1}$ , and 19.30 nm, respectively. However, in  $\text{Ag/CeO}_2$ , the surface area properties significantly change to  $42.57 \text{ m}^2 \text{ g}^{-1}$ ,  $1.228 \text{ cm}^3 \text{ g}^{-1}$ , and 11.74 nm, respectively. This noticeable change in structural characteristics is attributed to the introduction of Ag on the  $\text{CeO}_2$  surface, which agrees with the results from the previous studies.<sup>56</sup> The porosity and surface area of the material are maintained even after the introduction of Ag.

### 3.2 Electrochemical measurements (OER and HER)

**Oxygen evolution reactions (OER).** The electrocatalytic performance of  $\text{Ag/CeO}_2$  was evaluated for the oxygen evolution reaction (OER) *via* a three-electrode system in 1 M KOH solution using  $\text{Ag/AgCl}$  and Pt wire as the reference and counter electrodes, respectively. The working electrodes used were NiF, NiF/ $\text{CeO}_2$ , NiF/ $\text{CeO}_2$ /Light, NiF/ $\text{Ag/CeO}_2$ , and NiF/ $\text{Ag/CeO}_2$ /Light. The electrocatalytic performance was studied by linear sweep voltammetry (Table 1). The linear sweep voltammogram (LSV) for the OER performance of NiF, NiF/ $\text{CeO}_2$ , NiF/ $\text{CeO}_2$ /Light, NiF/ $\text{Ag/CeO}_2$ , and NiF/ $\text{Ag/CeO}_2$ /Light is shown in Fig. 5a. At a current density of  $10 \text{ mA cm}^{-2}$ , the overpotentials for NiF, NiF/ $\text{CeO}_2$ , NiF/ $\text{CeO}_2$ /Light, NiF/ $\text{Ag/CeO}_2$ , and NiF/ $\text{Ag/CeO}_2$ /

Fig. 3 (a) High-magnification FESEM images, (b) EDX elemental mapping, and (c) EDX spectrum of Ag/CeO<sub>2</sub> (inset: atomic and weight percentages of elements present in Ag/CeO<sub>2</sub> nanocomposites).

Fig. 4 (a) HRTEM image, (b) interplanar *d*-spacings, and (c) SAED pattern of Ag/CeO<sub>2</sub> nanocomposites.

Light were 730 mV, 620 mV, 560 mV, 500 mV, and 450 mV, respectively (shown in Fig. 5b). Fig. 5c illustrates the current density values for NiF, NiF/CeO<sub>2</sub>, NiF/CeO<sub>2</sub>/Light, NiF/Ag/CeO<sub>2</sub>, and NiF/Ag/CeO<sub>2</sub>/Light at a potential of 2.4 V. The corresponding current density values were 29 mA cm<sup>-2</sup>, 44.6 mA cm<sup>-2</sup>, 49.9 mA cm<sup>-2</sup>, 64.4 mA cm<sup>-2</sup>, and 86.7 mA cm<sup>-2</sup> (as shown in Fig. 5c). The lower overpotential and high current density signify enhanced OER performance of Ag/CeO<sub>2</sub> deposited on nickel foam (NiF/Ag/CeO<sub>2</sub>) compared to CeO<sub>2</sub> on nickel foam (NiF/CeO<sub>2</sub>). NiF/Ag/CeO<sub>2</sub> exhibited a 120 mV reduction in the

overpotential and a 19.8 mA cm<sup>-2</sup> increase in the current density compared to NiF/CeO<sub>2</sub>. This enhanced performance of NiF/Ag/CeO<sub>2</sub> can be attributed to the improved conductivity facilitated by Ag dispersed on the CeO<sub>2</sub> surface, leading to more efficient charge transfer processes (Fig. S8, ESI†). Furthermore, the overpotential and current density values suggest enhanced electrocatalytic performance of NiF/CeO<sub>2</sub> and NiF/Ag/CeO<sub>2</sub> by illuminating the electrodes with a monochromatic laser light source ( $\lambda = 405$  nm). This can be attributed to the dispersed Ag boosting the absorption of incident light, which consequently

Table 1 Summary of the OER performance of the electrocatalysts

Oxygen evolution reaction (OER)			
Catalyst	Overpotential at 10 mA cm <sup>-2</sup> (mV)	Tafel slope (mV dec <sup>-1</sup> )	Current density (mA cm <sup>-2</sup> )
NiF	730	461	29
NiF/CeO <sub>2</sub>	620	273	44.6
NiF/CeO <sub>2</sub> /Light	560	241	49.9
NiF/Ag/CeO <sub>2</sub>	500	226	64.4
NiF/Ag/CeO <sub>2</sub> /Light	450	158	86.7

facilitates the generation of electron-hole pairs in the conduction and valence bands, respectively. Moreover, with the band gap of Ag/CeO<sub>2</sub> being 2.90 eV, the illumination with light of 405 nm wavelength, which is equivalent to ~3.1 eV, facilitates the generation of electron-hole pairs, leading to an enhancement in its OER performance. However, since the band gap of CeO<sub>2</sub> (3.25 eV) is higher than that of Ag/CeO<sub>2</sub> (2.90 eV), the enhancement in the OER under illumination is less pronounced, as shown in Fig. 5a. Under light illumination, the overpotential of NiF/CeO<sub>2</sub> was reduced by 60 mV and the current density increased by 5.3 mA cm<sup>-2</sup>. Similarly, for NiF/Ag/CeO<sub>2</sub>, the overpotential decreased by 50 mV and the current

density dramatically increased by 22.3 mA cm<sup>-2</sup>. Fig. 5d presents the Tafel slopes (OER) for NiF, NiF/CeO<sub>2</sub>, NiF/CeO<sub>2</sub>/Light, NiF/Ag/CeO<sub>2</sub> and NiF/Ag/CeO<sub>2</sub>/Light. The Tafel slope was reduced significantly to 158 mV dec<sup>-1</sup> for NiF/Ag/CeO<sub>2</sub> in the presence of light, indicating its enhanced OER performance compared to NiF/Ag/CeO<sub>2</sub> with a Tafel slope of 226 mV dec<sup>-1</sup>, which is attributed to the enhanced reaction kinetics under light illumination and Ag doping. The reaction mechanism for the OER can be given by the following equations:<sup>57</sup>

Here, M represents the active site.

These charge carriers enhance the charge transfer process at the electrode-electrolyte interface, leading to improved reaction kinetics, lower overpotential, and increased current densities.<sup>58,59</sup>

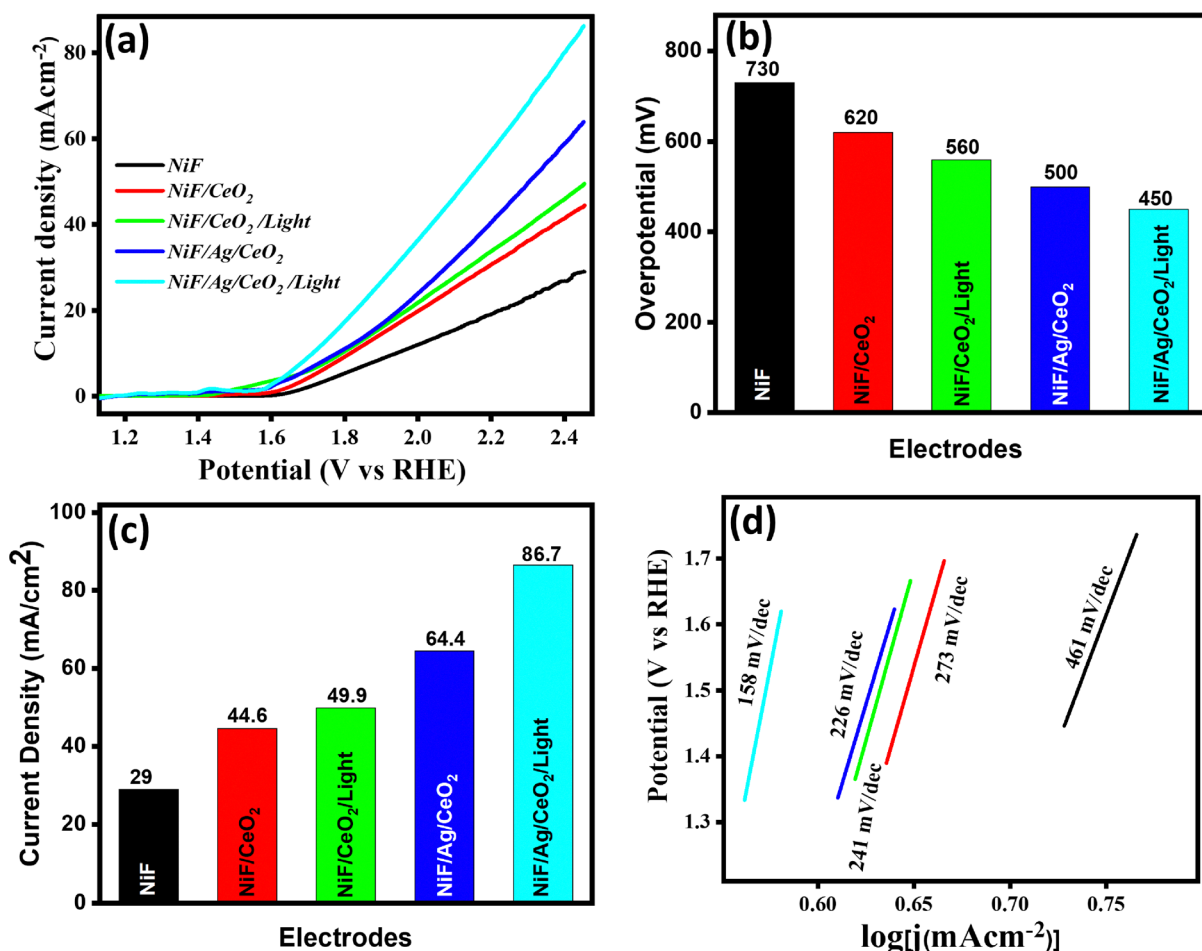

Fig. 5 (a) LSV curves, (b) overpotential (vs. RHE) at a current density of 10 mA cm<sup>-2</sup>, (c) current density at a potential of 2.4 V, and (d) the Tafel slope for the OER of NiF, NiF/CeO<sub>2</sub>, NiF/CeO<sub>2</sub>/Light, NiF/Ag/CeO<sub>2</sub>, and NiF/Ag/CeO<sub>2</sub>/Light.

Table 2 Summary of the HER performance of the electrocatalysts

Hydrogen evolution reaction (HER)			
Catalyst	Overpotential at 10 mA cm <sup>-2</sup> (mV)	Tafel slope (mV dec <sup>-1</sup> )	Current density (mA cm <sup>-2</sup> )
NiF	530	461	10.9
NiF/CeO <sub>2</sub>	410	238	21.2
NiF/CeO <sub>2</sub> /Light	330	219	25.3
NiF/Ag/CeO <sub>2</sub>	280	169	35.3
NiF/Ag/CeO <sub>2</sub> /Light	240	151	45.7

After investigating the OER performance, the electrocatalytic activity for the hydrogen evolution reaction (HER) of the electrodes, including NiF, NiF/CeO<sub>2</sub>, NiF/CeO<sub>2</sub>/Light, NiF/Ag/CeO<sub>2</sub>, and NiF/Ag/CeO<sub>2</sub>/Light, was also examined (Table 2). The LSV curves for the HER performance of NiF, NiF/CeO<sub>2</sub>, NiF/CeO<sub>2</sub>/Light, NiF/Ag/CeO<sub>2</sub>, and NiF/Ag/CeO<sub>2</sub>/Light are shown in Fig. 6a. The overpotentials calculated at a current density of -10 mA cm<sup>-2</sup> for NiF, NiF/CeO<sub>2</sub>, NiF/CeO<sub>2</sub>/Light, NiF/Ag/CeO<sub>2</sub>, and NiF/Ag/CeO<sub>2</sub>/Light were 530 mV, 410 mV, 330 mV, 280 mV, and 240 mV, respectively, and are shown in Fig. 6b. Fig. 6c illustrates the current density at 0.54 V for NiF,

NiF/CeO<sub>2</sub>, NiF/CeO<sub>2</sub>/Light, NiF/Ag/CeO<sub>2</sub>, and NiF/Ag/CeO<sub>2</sub>/Light. The values of current densities for NiF, NiF/CeO<sub>2</sub>, NiF/CeO<sub>2</sub>/Light, NiF/Ag/CeO<sub>2</sub>, and NiF/Ag/CeO<sub>2</sub>/Light were 10.9 mA cm<sup>-2</sup>, 21.2 mA cm<sup>-2</sup>, 25.3 mA cm<sup>-2</sup>, 35.3 mA cm<sup>-2</sup>, and 45.7 mA cm<sup>-2</sup>, respectively (as shown in Fig. 6c). For the HER as well, NiF/Ag/CeO<sub>2</sub> exhibited superior activity to NiF/CeO<sub>2</sub> with an overpotential reduction of 130 mV to achieve a 14.1 mA cm<sup>-2</sup> enhancement in the current density. Furthermore, the overpotential of NiF/CeO<sub>2</sub> was reduced by 80 mV, and the current density increased by 4.1 mA cm<sup>-2</sup> on illuminating NiF/CeO<sub>2</sub> with light. Similarly, for NiF/Ag/CeO<sub>2</sub>, the overpotential decreased by 40 mV and the current density dramatically increased by 10.4 mA cm<sup>-2</sup> under light illumination. Fig. 6d presents the Tafel slope (HER) for NiF, NiF/CeO<sub>2</sub>, NiF/CeO<sub>2</sub>/Light, NiF/Ag/CeO<sub>2</sub>, and NiF/Ag/CeO<sub>2</sub>/Light. The lowest Tafel slope (HER) was found to be 151 mV dec<sup>-1</sup> for NiF/Ag/CeO<sub>2</sub> in the presence of light. The reaction mechanism for the HER can be given by the equations:<sup>60</sup>

Fig. 6 (a) LSV curves, (b) overpotential (vs. RHE) at a current density of 10 mA cm<sup>-2</sup>, (c) current density at a potential of -0.54 V, and (d) the Tafel slope for the HER of NiF, NiF/CeO<sub>2</sub>, NiF/CeO<sub>2</sub>/Light, NiF/Ag/CeO<sub>2</sub>, and NiF/Ag/CeO<sub>2</sub>/Light.

The stability of NiF/Ag/CeO<sub>2</sub> in the presence of light was examined using the chronoamperometric study at a constant potential (1.56 V vs. RHE) in 1 M KOH solution (see Fig. S8b, ESI†). It was found that NiF/Ag/CeO<sub>2</sub> was stable for a time period of 2 hours.

#### Proposed mechanism for electrocatalytic water splitting.

Based on the results from the characterization techniques and electrocatalytic experiments, a possible mechanism was proposed to understand the electrocatalytic performance of Ag/CeO<sub>2</sub> electrocatalysts. Fig. 7 shows the schematic representation of the photoelectrocatalytic process taking place with the catalyst Ag/CeO<sub>2</sub>. Ag/CeO<sub>2</sub> outperforms pristine CeO<sub>2</sub> in the electrocatalytic performance for the OER and HER. Ag/CeO<sub>2</sub> exhibited a 120 mV reduction in the overpotential and a 19.8 mA cm<sup>-2</sup> increase in the current density compared to pristine CeO<sub>2</sub> for the oxygen evolution reaction. For the hydrogen evolution reaction, Ag/CeO<sub>2</sub> exhibited superior activity to pristine CeO<sub>2</sub> with a 130 mV reduction in overpotential and a 14.1 mA cm<sup>-2</sup> enhancement in the current density. The reduction in overpotential has been found to be more prominent in Ag/CeO<sub>2</sub> compared to other CeO<sub>2</sub>-based catalysts reported previously (Table 3). The distinctively high performance of Ag/CeO<sub>2</sub>, especially under light illumination, can be ascribed to the interaction between Ag and CeO<sub>2</sub> generating oxygen vacancies at the metal-support interface. The interaction of Ag and CeO<sub>2</sub> results in (i) a reduction in the band gap of CeO<sub>2</sub>, (ii) an improvement in light absorption, (iii) an enhancement in the absorption intensity through the localized surface plasmon resonance (LSPR)

**Table 3** Comparison of overpotential values for the HER and OER at a current density of 10 mA cm<sup>-2</sup> in 1 M KOH solution, as reported in the literature, for different CeO<sub>2</sub>-based catalysts

Catalyst	Reaction	Overpotential (mV)	
		@ 10 mA cm <sup>-2</sup>	Electrolyte Ref.

effect at the Ag/CeO<sub>2</sub> interface, (iv) an enhancement in the photogenerated electron-hole separation and (v) a delay in electron-hole recombination. The surface oxygen vacancies trap the photogenerated electrons causing a delayed recombination of photogenerated electron and hole pairs. This is supported by the drastic quenching of photoluminescence in Ag/CeO<sub>2</sub>. Note that the oxygen evolution reaction occurs in the spin triplet state. Therefore, the presence of spin-polarized electron ensembles can significantly influence the OER, particularly when the reaction cross section involves the transfer of spin-polarized electrons. In the present study, the spin polarization is due to the presence of oxygen vacancies that contribute to the localized spins trapped at the oxygen vacancy sites as has been reported by many researchers.<sup>61</sup>

**Fig. 7** Mechanism of the electrocatalytic water splitting.

## 4. Conclusion

In summary, we studied defects induced in ceria that could enhance electrocatalytic water splitting for the oxygen evolution reaction (OER) and hydrogen evolution reaction (HER). Ag/CeO<sub>2</sub> nanocomposites, prepared *via* a facile solvothermal method, exhibit outstanding electrocatalytic performance. The achieved high electrocatalytic activity can be ascribed to the interaction between Ag and CeO<sub>2</sub>, which increases the oxygen vacancies at the interface caused by the reduction of Ce<sup>4+</sup> to Ce<sup>3+</sup>. The oxygen vacancies at the Ag and CeO<sub>2</sub> interface facilitate photogenerated electron–hole pair separation, resulting in delayed recombination of electron–hole pairs. Raman spectroscopy, X-ray photoelectron spectroscopy, electron paramagnetic resonance spectroscopy and photoluminescence studies confirm the increase in oxygen vacancies in Ag/CeO<sub>2</sub>. Besides, the incorporation of Ag onto the surface of CeO<sub>2</sub> reduces the band gap and enhances light absorption, thereby contributing to the enhancement of photoelectrocatalytic activity. Compared to pristine CeO<sub>2</sub>, a remarkable enhancement in the electrocatalytic performance of Ag/CeO<sub>2</sub> shows the effect of Ag. The further enhancement of catalytic activity under light illumination reveals the superior photoelectrocatalytic properties of the Ag/CeO<sub>2</sub> composite. A drastic reduction in overpotential and an increase in current density are observed for Ag/CeO<sub>2</sub>. For the oxygen evolution reaction, Ag/CeO<sub>2</sub> exhibited a reduction of 120 mV in the overpotential and an increase of 19.8 mA cm<sup>-2</sup> in the current density compared to CeO<sub>2</sub>. For the hydrogen evolution reaction, Ag/CeO<sub>2</sub> exhibited a reduction of 130 mV in the overpotential and an increase of 14.1 mA cm<sup>-2</sup> in the current density. This work enhances the electrocatalytic performance of Ag/CeO<sub>2</sub> by combining oxygen vacancies with light-assisted catalysis. While many studies focus on either doping or structural modifications, our approach leverages both strategies to significantly increase active site density and improve charge transfer. The light activation further reduces the Tafel slope by 30% in the OER and 11% in the HER, boosting the efficiency of both the OER and HER in Ag/CeO<sub>2</sub>. Furthermore, Ag/CeO<sub>2</sub> was found to be stable for a duration of 2 hours under illumination. This synergistic approach can be used for utilizing Ag/CeO<sub>2</sub> as a promising material for photoelectrocatalytic water splitting. Moreover, we believe that the present work not only provides detailed insights into the characterization of defective ceria but also opens up possibilities to develop new ceria-based catalysts for efficient electrocatalytic splitting of water.
