Liquid phase epitaxy of CuGaO₂ on GaN: P–N heterostructure for photocatalytic water splitting†

Hadi Sena, *^{ab} Sho Kitano, ^c Hiroki Habazaki ^c and Masayoshi Fujii^{ab}

Semiconductor photocatalytic water splitting is a promising method to address the worldwide energy issues. Fast carrier recombination and the limited visible-light absorption are two main challenges to be overcome, and designing p–n heterojunctions is an effective solution. In this study, two direct band gap semiconductors are selected to form a p–n heterojunction. The results show that liquid phase epitaxy of a thick film p-type CuGaO₂ on an n-type GaN substrate is effective for the splitting of water into hydrogen and oxygen.

Introduction

Solar water splitting is a promising method for the direct conversion of solar energy into chemical fuels like hydrogen and oxygen. Photochemical water splitting is advantageous over photoelectrochemical water splitting, in which the counter electrode is mounted on the photocatalyst surface, known as the co-catalyst.^{1–3} Therefore, it is a cheap wireless reaction system, no external bias is required, and efficiency is not restricted by the low current conduction issues. The efficiency of most photocatalysts under sunlight is usually low because (i) they have a large band gap and they are not able to absorb visible light, which accounts for about 50% of the solar spectrum, (ii) the photocatalyst undergoes photo-corrosion after a certain period of reaction, (iii) photo-excited carriers recombine radiatively or non-radiatively before diffusing to the surface, usually being trapped at defect states, (iv) a severe upward band bending occurs at the surface of the n-type photocatalyst and the energy barrier caused by the band bending repels the photo-excited electrons toward the bulk region.^{4,5}

A p–n heterostructure consisting of p-type and n-type semiconductors in contact is an effective architecture for efficient charge separation and collection.^{6,7} They form a p–n junction with a space-charge region at the interface due to the diffusion of electrons and holes, creating a built-in potential. This built-in potential directs the electrons and holes to move in the opposite

direction. Upon irradiation by light sources with energies higher than the band gap, the photo-generated electron–hole pairs can be easily separated by the built-in electric field. As a consequence, the electrons are transferred to the conduction band of the n side and the holes to the valence band of the p side.

Copper gallium oxide (CuGaO₂) with the general structure of ABO₂ (A: Pt, Pd, Cu, Ag, and B: Al, Ga, In, Sc, Fe, Y, La) was first introduced by Omata *et al.*⁸ It was shown that CuGaO₂ had a direct band gap in the visible light region with a wurtzite crystal structure and p-type feature. Since then, the material has been mainly used as a solar cell absorber thanks to its high hole mobility and stability.^{9–11} In this study, we designed a p–n heterostructure of CuGaO₂ and gallium nitride (GaN). GaN is also a direct band gap semiconductor with an intrinsic n-type feature. It possesses remarkable electronic and optoelectronic properties, with a tunable direct band gap from 0.7 to 6.2 eV, and high-electron mobility ($> 10^3 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$). All these superior properties inspired us to design a p–n junction of two direct band gap semiconductors for efficient photocatalytic water splitting reaction. In this study, we will show how the p–n heterojunction is effective for water splitting hydrogen/oxygen generation reactions, while neither CuGaO₂ nor GaN are capable of splitting water efficiently.

Experimental section

CuGaO₂ thick films were grown by the liquid phase epitaxy method on a c-plane GaN wafer with a thickness of 420 μm, the dislocation density of $4.6 \times 10^6 \text{ cm}^{-2}$, miscut angle of 0.5° towards the 11–20 direction, and donor concentration of $3 \times 10^{16} \text{ cm}^{-3}$. Alumina crucibles were used to hold the growth solution and reactants, in which 99.9%-pure CuCl₂ was chosen as the bath solvent and Cu source. 5 mmol of Ga₂O₃ powder

(99.99% purity) was used as the solute and was mixed with 45 mmol CuCl_2 . The mixture of CuCl_2 and Ga_2O_3 was placed on the epi-ready GaN substrate, which was previously cut into a rectangle of 1×2 cm. The term “epi-ready” refers to the surface roughness of the substrate, which typically has a root mean square (RMS) value of less than 1 nm. No further polishing was performed on the substrate, and the film was grown on the substrate as purchased. The crucible was heated to 800°C at the rate of $40^\circ\text{C min}^{-1}$, held for 3 h, and cooled to room temperature at the rate of 2°C min^{-1} . The obtained powders and substrate were thoroughly washed with distilled water, and the substrate was further ultrasonicated in water for 10 min in order to make sure no unreacted powder was present on the surface of the substrate.

The surface morphology of the film was observed by a differential interference contrast (DIC) optical microscope, laser confocal imaging microscope, scanning electron microscope (SEM), and atomic force microscope (AFM) in tapping mode at the top view and the bird's eye view. X-ray diffraction (XRD) and Raman spectroscopy with a 532 nm laser were employed to identify the crystalline structure and orientation of the as-grown films and powders. The SEM equipped with an energy dispersive X-ray spectrometer (EDS) with a lateral resolution of 2 nm and an acceleration voltage of 20 kV was used for composition analysis. UV-Vis diffuse reflectance spectroscopy was used to estimate the band gaps. Photocatalytic hydrogen evolution was examined in a solution of 50 mg powder or $1 \text{ cm} \times 2 \text{ cm}$ substrate, 0.5 mL CH_3OH , 4.5 mL H_2O and 133 μL $\text{H}_2\text{PtCl}_6 \cdot 6\text{H}_2\text{O}$ (19.5 mM) under a Xenon light source. The photocatalytic reaction for O_2 evolution from an aqueous silver nitrate solution (0.05 mol L^{-1}) was carried out in a test tube. For both tests, Ar gas was bubbled for 30 min for removing air dissolved in water. The temperature of the reactions was maintained at room temperature by using a water bath. The quantity of the evolved gases was determined by a gas chromatograph (thermal conductivity detector; molecular sieve 5 Å column packing with Ar carrier gas for H_2 test, and He carrier gas for O_2 test). A schematic illustration of the experiment setup is shown in Fig. S1 (ESI[†]). The apparent quantum efficiency (AQE) was evaluated using a 380 nm monochromatic light source. The active surface area of the samples was measured by the adsorption isotherms of N_2 at 77 K by the Brunauer–Emmett–Teller (BET) method. Cathodoluminescence (CL, LS-100-EM-TYPE2, HORIBA) attached to the FE-SEM was measured under 15 kV at room temperature for the estimation of the carrier recombination rate.

Results and discussion

Fig. 1 shows a 3D bird's eye view image of CuGaO_2 film grown on the GaN substrate observed by a DIC optical microscope and laser microscope. It is evident that the epitaxial structures are grown perpendicular to the 0001 plane of the GaN substrate with the root mean square (RMS) surface roughness of 260 nm in the scan area of $256 \mu\text{m} \times 256 \mu\text{m}$. The surface roughness was well consistent with the AFM results, where the roughness was estimated to be 277 nm in the scan area of $2 \mu\text{m} \times 2 \mu\text{m}$, as shown in Fig. S2 (ESI[†]).

Fig. 1 Bird's eye view images from a (a) differential interference contrast optical microscope, and (b) laser confocal imaging microscope.

X-ray diffractions of (0002) and (0004) due to the GaN substrate are obvious in Fig. 2a. However, due to the extremely high intensity of the substrate other peaks are difficult to confirm. Therefore, the intensity of the XRD profile is plotted in the log scale in Fig. S3 (ESI[†]). Most XRD diffractions observed in Fig. S2 (ESI[†]) were assigned to the wurtzite CuGaO_2 ; however, it is evident that some minor peaks related to Ga_2O_3 are also present due to the unreacted Ga_2O_3 . The Rietveld analysis showed the molar fraction of CuGaO_2 : Ga_2O_3 = 86.1%: 13.9% on the surface of the GaN substrate. The digital photograph of the as-grown substrate is also shown in the inset. The brown color of the substrate suggests that the band gap of the film is smaller than 2 eV. It is noticed that the powder synthesized inside the crucible had a composition of CuGa_2O_4 with a spinel crystal structure, with a small amount of unreacted Ga_2O_3 as shown by star markers in Fig. S4 (ESI[†]). The BET surface area of the powder was $2.0592 \text{ m}^2 \text{ g}^{-1}$. CuGa_2O_4 is also another interesting p-type material for photocatalytic properties; however, it is not clear why wurtzite CuGaO_2 is grown on the GaN substrate, while spinel CuGa_2O_4 is synthesized in the powder form. One reason may be due to the fact that CuGa_2O_4 requires more oxidizing environment than CuGaO_2 and the nucleation of CuGaO_2 seeds is more probable to occur on the

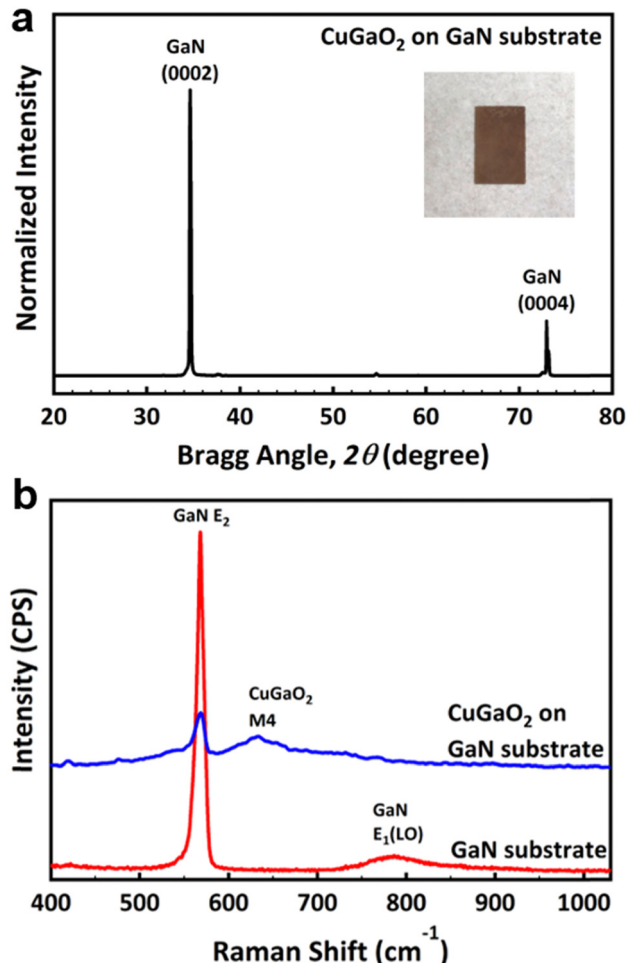

Fig. 2 (a) XRD profile of a CuGaO₂ film grown on the GaN substrate with a digital photograph of it in the inset, and (b) Raman spectra of the GaN substrate before and after epitaxial growth.

nitride substrate than the bulk. SEM micrographs of the CuGa₂O₄ powder are shown in Fig. S5 (ESI†).

The Raman profile of the GaN substrate shows typical *c*-plane GaN Raman modes of E₂ at 568 cm⁻¹, and A₁(LO) at 786 cm⁻¹. After the growth, however, the M₄ Raman mode of CuGaO₂ appeared at 635 cm⁻¹ in addition to the Raman mode of the substrate, as shown in Fig. 2b.¹² Considering the fact that the penetration depth of the 532 nm laser is less than 1 μm, the presence of GaN Raman peaks after growth means that the substrate is not fully covered by the film, or due to the morphology of the grains the penetration depth nominally gets larger as compared to the case if we had a uniform thickness structure. From the SEM cross-section image, it is confirmed that the thickness of the film on the substrate is about 10 μm, as shown by the green rectangle in Fig. 3a. The surface of the film observed by SEM is shown in Fig. 3b and corresponding EDS elemental mappings of Cu Kα, Ga Kα, and O Kα confirm the presence of each element on the film structure.

Fig. 4a shows the UV-Vis diffused reflectance spectra of the GaN substrate before and after growth. In both samples below a certain wavelength, known as the absorption edge, an intense absorption occurs. It is obvious that the absorption edge of the

GaN substrate is 380 nm, while it shifts to the visible light region and reaches 670 nm after the growth of CuGaO₂. No appreciable tail absorbance at wavelengths higher than the absorption edge is observed due to the existence of oxygen/copper vacancies or other types of defects that form localized states in the band gap. The absence of defects is beneficial for photocatalytic properties, leading to the longer lifetime of electron/hole carriers. Moreover, the high absorption intensity in both samples suggests that the electronic transition is direct. The band gap of the samples is estimated by Kubelka–Munk theory and summarized in Fig. 4b and c. The theory is based on eqn (1), where α is absorption coefficient, h is Planck's constant, and ν is light frequency. n can take on values of 3, 2, 3/2, or 1/2, corresponding to indirect (forbidden), indirect (allowed), direct (forbidden), and direct (allowed) transitions, respectively. These plots of $(\alpha h\nu)^n$ versus $h\nu$ yield the value of the band gap when extrapolated to the baseline. The estimated band gaps are 3.40 eV and 1.84 eV for the GaN substrate and CuGaO₂ on GaN, respectively. The estimated band gap for the GaN substrate is consistent with the reported values. The band gap of the sample after epitaxial growth was in good agreement with the reported value in the literature, 1.47 eV.⁸

$$\alpha h\nu = (h\nu - E_g)^{1/n} \quad (1)$$

Photocatalytic water splitting hydrogen production test results are shown in Fig. 5a. It is shown that while the p-type powder has no activity under irradiation, the p-n heterostructure CuGa₂O₄/GaN sample generates hydrogen under the presence of a hole scavenger sacrificial agent. The apparent quantum efficiency (AQE) measured under 380 nm monochromatic light also improved from 0% to 1.1% for the p-n heterostructure sample. Further studies are required for investigating the effect of the cocatalyst on the photocatalytic activity. Loading various types of cocatalysts such as Pt, RuO₂, or Rh/Cr₂O₃ particles *via* the impregnation method can significantly improve the efficiency of the photocatalytic reaction. The stability of the CuGa₂O₄/GaN sample was examined by cyclic photocatalytic test, as shown in Fig. 5b. It is shown that the amount of hydrogen production is reasonably similar for three cycles, indicating the potential of the p-n heterostructure for long-term photocatalytic activity. Moreover, the examination of the sample by XRD analysis before and after the photocatalysis test confirmed that the photocatalyst is stable under light irradiation, as shown in Fig. S6 (ESI[†]). The deposition of Pt cocatalysts on the surface of the film is confirmed to be successful, as shown in Fig. S7 (ESI[†]). Photocatalytic water splitting oxygen production test results are shown in Fig. 5c. It is evident that while p-type powder is effective for water splitting in the presence of Ag⁺ ions as an electron scavenger, the CuGa₂O₄/GaN sample shows a six times higher oxygen generation rate. The higher rate of both hydrogen and oxygen generation for the CuGa₂O₄/GaN sample with respect to the powder can be attributed to the effective charge separation of the electrons and holes in the proposed p-n heterostructure. The AQE was 2.9%, which is considered a relatively high efficiency. To compare

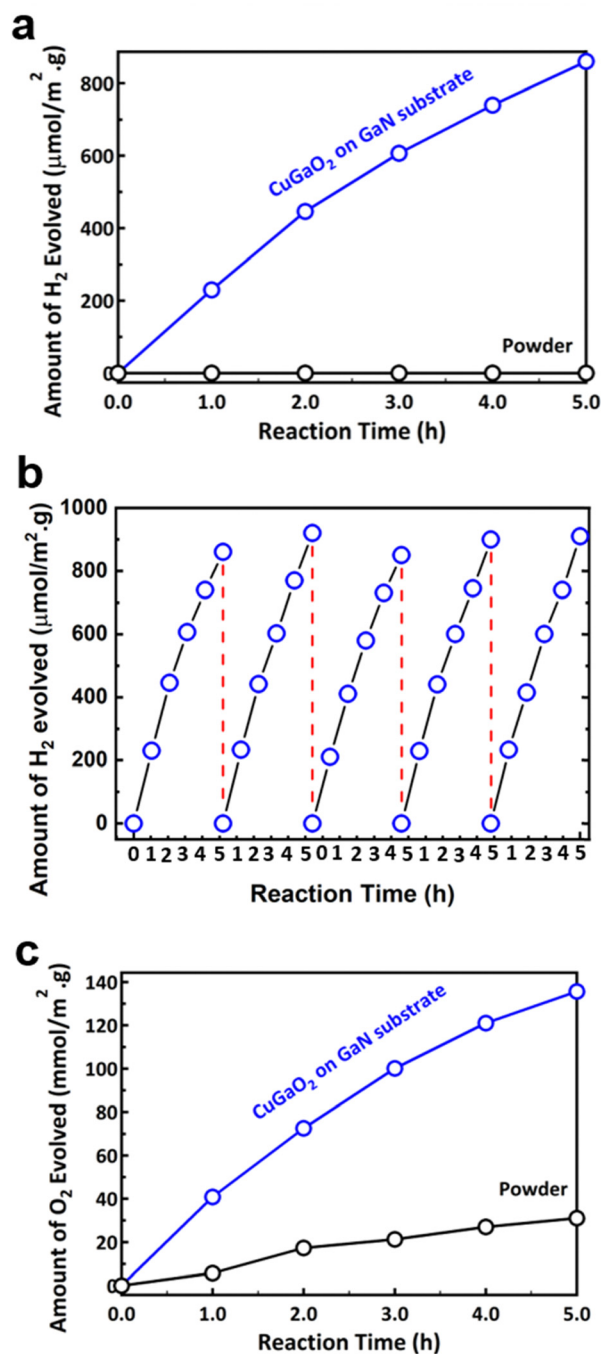

Fig. 5 (a) Photocatalytic hydrogen generation of powder and CuGa₂O₄ on GaN samples, (b) three cycles for the stability test of hydrogen generation of the CuGa₂O₄ on GaN sample, and (c) photocatalytic oxygen generation of powder and CuGa₂O₄ on GaN samples.

CuGa₂O₄/GaN with CuGaO₂ instead of CuGa₂O₄ powder produced inside the crucible, we also synthesized the CuGaO₂ by a hydrothermal method, as explained in the ESI[†]. The XRD profile shown in Fig. S8 (ESI[†]) is in good agreement with the hexagonal CuGaO₂ with the space group of *P6₃/mmc*. As shown in Fig. S9 (ESI[†]), the photocatalytic hydrogen generation of the CuGaO₂ was slightly better than that of CuGa₂O₄, both of which are much lower than the CuGaO₂/GaN sample.

Fig. 6 Cathodoluminescence spectra acquired for each sample.

Fig. 6 shows the cathodoluminescence spectra of the GaN substrate and CuGaO₂/GaN substrate. The sharp luminescence at 364.5 nm (3.4 eV) corresponds to the band gap of the GaN substrate. Its intensity is lower for the CuGaO₂/GaN sample due to the efficient transfer of electrons from n-type GaN to the p-type CuGaO₂ film. Less electron/hole recombination leads to a lower intensity of the CL. At the p–n junction and in equilibrium, electrons in the n-type GaN move to the p-side filling some of the holes in the p-type CuGaO₂ due to the difference in Fermi levels of the two semiconductors. This causes an electric field at the junction. When irradiated with light, electrons will excite from the VB to the CB of each semiconductor, and because of the internal electric field, electrons will move from the CB of CuGaO₂ to the CB of the GaN, and holes move from the VB of GaN to the VB of the CuGaO₂. In this manner, the photogenerated electron–hole pairs are effectively separated by the p–n junction, and a high concentration of electrons is obtained in the CB of GaN, and a high concentration of holes is obtained in the VB of CuGaO₂. The mechanism explains the effectiveness of the p–n heterostructure in charge separation of carriers; however, further studies are required for the calculation of the band structure of this p–n heterostructure. Also, we believe that this study, coupled with other well-known approaches like the Step-scheme (S-scheme), Z-scheme, and photoelectrochemical (PEC) approach, can open a new door for efficient photocatalyst development in the future.^{13–16}

Conclusions

In summary, a p–n heterostructure of CuGaO₂/GaN was designed for water-splitting reaction. The film was grown perpendicular to the GaN *c*-plane. The band gap was shown to be in the visible region, 1.84 eV. The water splitting reaction showed hydrogen generation of ~800 μmol h⁻¹ and oxygen generation of ~120 mmol h⁻¹. It was shown that the p–n heterostructure was effective for the charge separation of carriers for acquiring a high-efficiency photocatalyst.
