Surface chemistry dictates the optoelectronic properties of semiconductor quantum dots (QDs). Tailoring these properties relies on the meticulous selection of surface ligands for efficient passivation. While long-chain organic ligands boast a well-understood passivation mechanism, the intricacies of short inorganic ionic ligands remain largely unexplored. This study sheds light on the surface-passivation mechanism of short inorganic ligands, particularly focusing on SCN⁻ ions on CdSe QDs. Employing steady-state and time-resolved infrared spectroscopic techniques, we elucidated the surface-ligand interactions and coordination modes of SCN⁻-capped CdSe QDs. Comparative analysis with studies on CdS QDs unveils intriguing insights into the coordination behavior and passivation efficacy of SCN⁻ ions on Cd²⁺ rich QD surfaces. Our results reveal the requirement of both surface-bound (strong binding) and weakly-interacting interfacial SCN⁻ ions for effective CdSe QD passivation. Beyond fostering a deeper understanding of surface-ligand interactions and highlighting the importance of a comprehensive exploration of ligand chemistries, this study holds implications for optimizing QD performance across diverse applications.

Introduction

Colloidal quantum dots (QDs) have captured significant interest due to their unique electronic and optical properties, which can be tailored for specific applications through precise control over material selection, size, shape, and surface ligands.^{1–4} The high surface-to-volume ratio of QDs renders their properties susceptible to the nature of the surface.^{5,6} Surface-passivating ligands play a critical role in determining the QD quality, stability, and overall physical and chemical properties.⁷

Among various QDs, cadmium selenide (CdSe) stands out for its size-tunable properties. However, long-chain organic ligands, commonly used during synthesis for nucleation and growth control (*e.g.*, oleic acid), act as insulators, preventing close proximity of QDs and limiting their device potential.^{8,9} Ligand exchange strategies with shorter inorganic ligands have emerged as a promising approach for overcoming this limitation. These shorter ligands influence carrier mobility by alter-

ing the inter-QD dielectric environment and tunneling distance.¹⁰ Mobility increases significantly with decreasing ligand length, highlighting the advantage of short inorganic ligands like thiocyanate (SCN⁻) for enhancing electronic coupling between adjacent QDs, a crucial factor for device fabrication.^{2,11–15}

Recent studies have demonstrated the effectiveness of thiocyanate (SCN⁻) anions as short capping ligands to improve device performance.^{2,14} While extensive research using ¹H NMR spectroscopy has elucidated the interaction between oleic acid and CdSe QDs,^{5,16–19} the lack of hydrogen atoms in SCN⁻ ions prevents the use of this technique. This presents a significant challenge in understanding how SCN⁻ stabilizes QDs in solution, a crucial aspect for optimizing device performance.

In contrast to ¹H NMR, SCN⁻ exhibits a distinct spectroscopic signature in the mid-IR region due to its nitrile (C≡N) stretching. This stretching is sensitive to the local environment and features a high extinction coefficient. The C≡N stretching has been widely used as a spectroscopic reporter to probe the interaction of SCN⁻ with condensed-phase media, biomolecules, and materials, including QDs.^{1,3,20–24} For example, in a previous study on QDs, Kagan and coworkers reported two SCN⁻ populations (directly bound and freely diffusing) for SCN⁻-capped CdSe QDs.²

Our recent work on SCN⁻-capped CdS QDs employed FTIR and time-resolved vibrational spectroscopy to identify the ligand populations required for surface passivation.¹ We observed correlations between the ligand fluctuation dynamics

timescales and the strengths of the surface–ligand interactions. This revealed three distinct ligand populations: directly bound, weakly bound, and freely diffusing. Theoretical calculations further predicted that directly bound ligands bind to the Cd²⁺ rich (111) facet. Since Cd²⁺ is the preferred binding facet for SCN[−] in both CdS and CdSe QDs, a thorough investigation of SCN[−]-capped CdSe QDs is crucial to understanding the binding nature and the coordination modes of the ligands.

This work utilizes FTIR and two-dimensional infrared (2D IR) spectroscopic techniques to reveal the surface passivation mechanism of SCN[−]-capped CdSe QDs. We compare the surface–ligand interactions observed here with those previously reported for CdS QDs.¹ Our findings reveal remarkable similarities between the two systems suggesting a potentially universal binding mechanism for SCN[−] on CdX (X = S and Se) QDs. Our results suggest the need for both direct surface binding and interfacial ligands for the effective passivation of CdX.

Furthermore, the presence of interfacial ions not directly bound to the QD facet suggests the formation of a double layer. While the concept of double layer formation (electrostatic interaction) for small inorganic QD ligands has been proposed in the literature,^{12,15,25–28} no experimental evidence has been presented to date. Our findings provide the experimental evidence of double layer formation for surface–ligand interactions in SCN[−]-capped CdSe and CdS QDs.

Experimental

Chemicals

Cadmium oxide (CdO 99.5%), trioctylphosphine oxide (TOPO 99%), trioctylphosphine (TOP 90%), 1-octadecene (ODE 90%), oleic acid (OA 90%), selenium powder mesh (99.99%), octadecylamine (ODA >95%), toluene, hexane, methanol, acetone and chloro propanethiol (CPT) were used.

SCN[−]-capped CdSe nanocrystal synthesis

At first, CdSe QDs were synthesized, which were further used to prepare SCN[−]-capped CdSe QDs *via* ligand exchange. For the synthesis of CdSe QDs, 1 mmol CdO and 4 mmol OA were added to 14 mL of ODE in a 50 mL four-necked round bottom flask. Initially, the reaction mixture was degassed at room temperature for 5 min and then the temperature was increased to 120 °C under vacuum and degassed for 30 min. After that, under an inert atmosphere the temperature was raised to 240 °C while maintaining constant stirring until a clear solution was obtained. The temperature of the solution was then brought to 90 °C, followed by the addition of ODA (1.5 g) and TOPO (1 g) to the solution and heated again to 280 °C with continuous stirring under an inert atmosphere. At this temperature the TOP-Se solution (0.4 M, 2.5 mL) was injected swiftly into the Cd-oleate solution. The temperature fell down to 268 °C and the reaction was allowed to proceed at 270 °C until the desired size of the nanocrystals was achieved. The QDs were purified by phase separation with a 1 : 1 mixture of

hexane and methanol to remove unreacted precursors. The QDs were precipitated by adding acetone followed by centrifugation and finally redispersed in hexane.^{29–32}

The ligand exchange procedure, following the method reported by Kagan *et al.*² with some modifications, involved preparing a 1 mL solution of 130 mM NH₄SCN in acetone. This solution was added dropwise to 0.5 mL of a dispersion of as-synthesized CdSe quantum dots in hexane (15–20 mg mL^{−1}) until precipitation occurred. The resulting solution underwent centrifugation for 3 minutes at 4000 rpm. The supernatant was then discarded, and the resulting quantum dots were washed with acetone. Finally, the CdSe quantum dots were dried and dispersed in 0.5 mL of DMF with 0.5 μL of CPT. The SCN[−]-capped CdSe was utilized for spectroscopic studies.

Material characterization

Optical absorption measurements were conducted using a Shimadzu UV-vis-IR (UV-3600 Plus) spectrophotometer. High-resolution images of the quantum dots were obtained using a high-resolution transmission electron microscope (HRTEM, JEOL JEM 2200FES). Powder X-ray diffraction (PXRD) patterns were collected using a Bruker D8 Advance diffractometer in the Bragg–Brentano geometry and operated with Cu K α radiation.

Quantum calculations

To replicate the experimental conditions, plane-wave density functional theory (DFT) calculations were carried out using Quantum Espresso on the (111) facet of zinc blende-shaped CdSe QDs.³³ For simplicity, a slab model was used to optimize the QD structure. The PBE exchange–correlation functional was employed, with ultrasoft pseudopotentials describing the electron–ion interactions.^{34,35} To calculate the C≡N stretching frequency, small fragments of the slab were analyzed at the B3LYP/lanl2dz level using the Gaussian 16 package.³⁶

IR spectroscopy

IR absorption spectra were recorded at room temperature using a Bruker Vertex 70 FTIR spectrometer. Each sample involved loading approximately 90 μL of the sample solution into a demountable cell comprising two windows (CaF₂, 3 mm thickness) separated by a mylar spacer of 100 μm thickness. The same sample cell was employed for 2D IR experiments.

2D IR spectroscopy

The 2D IR spectra were acquired using a pulse shaper-based 2D IR spectrometer developed by PhaseTech Spectroscopy, Inc., USA. A detailed description of the setup employed in this study has been provided elsewhere.³⁷ In brief, mid-IR pulses, centered at ~2070 cm^{−1}, were generated with an approximately ~60 fs pulse width. A beam splitter was used to split the mid IR pulse into a strong pump (80%) beam and a weak probe (20%) beam. A germanium acoustic-optic modulator (AOM) based pulse shaper was used to generate two pump pulses with a delay interval of τ from a single strong pump pulse. The spatially and temporarily overlapped pump and probe pulses

were directed toward the sample using parabolic mirrors. A motorized delay stage was used to set the pump and probe delay (T_w). Each 2D IR spectrum was acquired by scanning τ at a fixed T_w . The signal was collected using a monochromator (Princeton Instruments) and detected on a nitrogen-cooled 64-pixel HgCdTe (MCT) IR array (InfraRed Associates) detector. The final 2D IR spectra were constructed by Fourier-transforming the experimental data along the axis. Generally, a 2D IR spectrum is a plot of the initial frequencies *versus* the final frequencies. The 2D IR experiments were conducted using the same solutions used for FTIR in the same sample cell.

The waiting time dependence of the 2D IR lineshapes was analyzed employing the center line slope (CLS) method, and the CLS decays were fitted to multi-exponential decay functions.³⁸ While calculating the CLS from the central part of the peak is standard practice for single or non-overlapping spectral bands, spectral overlap can cause potential distortion in the spectrum, leading to significant errors in the calculated CLS timescales. For overlapping bands, it has been shown that CLS can still be accurately calculated separately from the individual peaks if the CLS is calculated to the blue of the peak center for the high-frequency spectral band and to the red of the peak center for the low-frequency spectral band.³⁹ Through 2D IR spectral simulations, we identified the spectral regions for each of the overlapping peaks that provide the lowest error (<5%) in the calculated CLS.

Results and discussion

Fig. 1a illustrates the UV-vis spectra of oleate-passivated CdSe QDs dispersed in hexane (prior to ligand exchange) and SCN⁻-capped CdSe QDs in dimethylformamide (DMF) solution (following ligand exchange). Notably, the characteristic excitonic peaks of the CdSe QDs remained unchanged after ligand exchange. The X-ray diffraction (XRD) pattern of the SCN⁻-capped CdSe QDs closely resembled that of the oleate-capped ones (Fig. 1b), with prominent peaks at angles (2θ) 24.9°, 41.5°, and 49.2° corresponding to the (111), (220), and (311) planes of the zinc blende structure, consistent with prior literature findings.^{40,41} This analysis confirms the preservation of crystallinity and the predominance of (111) facets in the QDs before and after ligand exchange. The XRD pattern was slightly noisier after the exchange process because the recovered sample was smaller. Fig. 1c presents a high-resolution transmission electron microscopy (HRTEM) image of CdSe QDs before ligand exchange. The size distribution is shown in Fig. 1d. As the UV-vis spectrum barely changes before and after exchange, the particle size is expected to remain the same.

We obtained the FTIR spectrum of the C≡N stretching for the SCN⁻-capped CdSe QD colloidal solution in DMF (Fig. 2a). Notably, the C≡N stretching spectrum exhibits an asymmetric band, manifesting a shoulder on the high-frequency side, indicative of a blue shift. The spectrum was fitted to two Gaussians centered at 2056 cm⁻¹ (peak A, FWHM = 15.5 cm⁻¹)

and 2072 cm⁻¹ (peak B, FWHM = 11.4 cm⁻¹). To ascertain the C≡N stretching peak of free SCN⁻ in DMF in the absence of QDs, we recorded the FTIR spectrum of NH₄SCN dissolved in DMF (Fig. 2b). This spectrum revealed a symmetric peak at 2056 cm⁻¹ (peak A', FWHM = 13 cm⁻¹). Although a peak at 2056 cm⁻¹ is observed in both the presence and absence of the QDs, the peak exhibits a larger FWHM in the presence of QDs. Our FTIR results in the presence of QDs align well with the previously reported C≡N stretching spectrum of SCN⁻-capped CdSe QDs in DMSO.² While the solvent change from DMSO to DMF slightly affects the peak positions, the overall spectral shape with two overlapping peaks remains consistent. In the previous report, the high-frequency peak in DMSO was assigned to the ionically bound SCN⁻ ions at the positively charged sites (111 facet) on the CdSe surface, while the low-frequency peak was assigned to the free SCN⁻ ions.² Interestingly, identical C≡N stretching peak positions were reported for a different SCN⁻-capped QD (CdS) colloidal solution in DMF.¹

An approximately 3 cm⁻¹ increase in the FWHM of the peak at 2056 cm⁻¹ was observed in the presence of QDs, compared to that observed in the absence of QDs, for both CdSe and CdS QDs. Plane-wave DFT calculations were performed to optimize the structure of the SCN⁻-bound CdSe crystal (Fig. 2c). Frequency calculations of CdSe QDs estimated the C≡N stretching frequency of the nitrogen-bound SCN⁻ to the Cd²⁺ rich (111) facet of the quantum dot to be ~2083 cm⁻¹. This result is consistent with the plane-wave DFT calculations on CdS QDs, which show a frequency of 2079.3 cm⁻¹.¹ The close similarity of the estimated C≡N stretching frequencies and the comparable high-frequency peak positions between CdS and CdSe QDs indicate that the 2072 cm⁻¹ peak in CdSe QDs arises from the SCN⁻ bound to the (111) facet, directly through the nitrogen atom. Previous literature has also attributed the SCN⁻ peak at ~2072 cm⁻¹ to N-bound coordination to Ag nanoparticles.⁴²

The FTIR spectra of SCN⁻-capped CdSe QDs reveal the presence of two distinct SCN⁻ populations, previously identified as bound and free ligands.² However, despite exhibiting nearly identical lineshape and peak positions in the FTIR, recent time-resolved IR studies on SCN⁻-capped CdS QDs unveiled the necessity for three distinct SCN⁻ populations (directly bound, weakly bound, and free anions) to effectively passivate the CdS QD surface.¹ This observation prompted us to investigate whether the surface passivation mechanism observed in SCN⁻-capped CdSe QDs mirrors that of SCN⁻-capped CdS QDs. We conducted additional time-resolved IR studies to elucidate any similarities or differences in the surface passivation mechanisms between the two systems.

We used 2D IR spectroscopy to investigate the interaction between SCN⁻ ligand CdSe QDs. 2D IR spectra were recorded for both free SCN⁻ and SCN⁻-capped CdSe quantum dot colloidal solution in DMF at various time delays (T_w) (Fig. 3). A typical 2D IR spectrum, corresponding to a single peak in the FTIR spectrum, comprises a peak pair, originating from $\nu = 0$ to $\nu = 1$ (blue) and $\nu = 1$ to $\nu = 2$ (red) coherences. The differ-

Fig. 1 (a) UV-vis absorption spectra of oleate-capped CdSe QD colloidal solution in hexane and thiocyanate SCN^- -capped CdSe QD colloidal solution in DMF. (b) Diffraction patterns of QDs before and after ligand exchange revealing identical crystallinity. (c) HRTEM image of CdSe QDs before ligand exchange. (d) Particle size distributions with peaks at around ~ 3 nm are obtained from the HRTEM analysis of CdSe QDs.

ence in the peak positions along the detection frequency (x-axis) represents the anharmonicity of the vibrational mode. At early time delays, the peak pairs are elongated due to a strong correlation between excitation and detection frequencies. As T_w increases, the correlation weakens, and the peak shapes become broader until they are circular, indicating a complete loss of correlations.

The FTIR spectrum (Fig. 2a) of the SCN^- -capped CdSe QDs in DMF exhibits two peaks. Consequently, the corresponding 2D IR spectra consist of 2 peak pairs (marked as A and B). Peak pair A corresponds to the FTIR peak at 2056 cm^{-1} and peak pair B corresponds to the FTIR peak at 2072 cm^{-1} . Established analysis methods, such as center line slope (CLS)³⁸ or nodal line slope (NLS)⁴³ analysis, provides T_w -dependent changes in peak shapes. Through 2D IR spectral simu-

lations, we identified the spectral regions for each of the overlapping peaks such that the CLS values and their time dependence are devoid of any potential distortions that may arise from the overlap of the two spectral bands (Fig. S2 and S3†). This allows us to extract the underlying fluctuation timescales for each FTIR peak through frequency-frequency correlation functions (FFCF).

The analysis of peak pairs A and B is shown in Fig. 4. Both peaks exhibit a fast time constant of ~ 1 ps. Additionally, peak A shows a bi-exponential decay with two time-constants of 4.9 ps and 60 ps, while peak B shows another timescale with a time constant of 120 ps (see the ESI†). In the absence of QDs (bulk DMF), the FFCF extracted from freely diffusing SCN^- ions (peak A') in bulk DMF also shows an ~ 1 ps timescale dynamics and further decays rapidly at a timescale of ~ 6.8 ps.

Fig. 2 (a) The FTIR spectrum of the C≡N stretching for SCN⁻-capped CdSe QD colloidal solution in DMF shows two overlapping transitions (A and B). (b) The FTIR spectrum of the C≡N stretching for SCN⁻ in the absence of QDs shows a single symmetric peak (A'). (c) The optimized slab structure of the nitrogen terminated SCN⁻-capped (111) facet of the CdSe crystal.

Fig. 3 2D IR spectra of NH₄SCN (left column) and CdSe-SCN (right column) in DMF at three different waiting times (T_w). T_w increases from the top to the bottom along each column.

This timescale reflects the solvent fluctuations around the free SCN⁻ ion. Prior studies have proposed various timescales for DMF fluctuations (1–10 ps).^{1,44,45} This suggests that free SCN⁻ ions in bulk DMF experience very rapid fluctuations in their vibrational frequencies.

When SCN⁻ interacts with another species, its frequency fluctuations should slow down. The strength of the interaction determines the extent of the slowdown. Peak B, with the slowest timescale, corresponds to SCN⁻ directly bound to the (111) facet of the CdSe QDs. This direct attachment likely creates the strongest interaction between the QDs and the SCN⁻ ligands, resulting in the slowest fluctuation timescale.

Fig. 4 T_w -dependent CLS of the 2072 cm⁻¹ peak in SCN⁻-capped CdSe QDs corresponding to the bound ligands (green) shows the slowest decay and that of the 2056 cm⁻¹ peak corresponding to the free ions (blue) in the absence of QDs shows the fastest decay. The CLS decay of the 2056 cm⁻¹ peak in the presence of CdSe QDs shows a bi-exponential decay.

The observed timescale of ~120 ps for bound SCN⁻ ions on the CdSe (111) facet is slightly slower than that reported for SCN⁻-capped CdS QDs.¹ This suggests a subtle difference in the surface–ligand interaction between CdSe and CdS QDs, despite both involving the Cd²⁺ rich (111) facet. Similar observations have been reported for the binding energies of oleic acid bound to the surface of these two QDs.⁴⁶

The dynamics of small anionic ligands contribute negligibly to their own spectral diffusion.⁴⁷ This raises the question: how are surface–SCN⁻ interactions related to the slowing down of SCN⁻ FFCF decay timescales? Solvent molecules in contact with or near the interface exhibit different dynamical properties. The structural dynamics of the solvent molecules

become faster as they move away from the interface, causing the SCN^- frequency fluctuation to become faster with increasing distance from the QD surface.⁴⁸ Additionally, the proximity of bulky, slowly moving QDs compared to small solvent molecules further slows the fluctuation timescale near the QD surface.

Thus, the fluctuation timescales of the ligands serve as indicators of surface–ligand interactions. In simpler terms, stronger interactions lead to slower timescales. Interestingly, in addition to the fast timescale of ~ 1 ps, peak A exhibits two distinct time constants. In general, a multiexponential decay of CLS is attributed to different types of motions in the surrounding environment happening at different timescales. However, one of these timescales matches with the time constant obtained for peak A' in the absence of QDs. Since the peak position is the same for peak A and peak A', an additional timescale likely indicates the presence of two different SCN^- populations within peak A. One population exhibits the timescale of free SCN^- ions in bulk DMF (~ 4.9 ps). The other population shows a timescale of about ~ 60 ps, which is in between that of free ligands and those directly bound to the QD surface. This intermediate timescale implies that these SCN^- ions are neither in the bulk nor directly bound to the QD surface.

SCN^- ions can interact with either NH_4^+ counter-cations or the QD surface in the colloidal solution. The possibility of NH_4^+ slowing down the fluctuation dynamics can be excluded because the cation was present even in the absence of QDs, where an ultrafast fluctuation timescale of 6.8 ps was observed. Therefore, the significant retardation (\sim ten-fold) in fluctuation dynamics is attributed to the interactions between the ligands and the QD surface. The timescale of 60 ps suggests that these ions are not directly bound to the Cd^{2+} rich (111) facet. Since anions like SCN^- typically exhibit X-type ligand behavior, they are unlikely to interact with the neutral facets of the QDs.⁴⁹

The intermediate timescale of 60 ps may suggest a weaker interaction between the ligands and the Cd^{2+} rich (111) facet. In other words, the SCN^- ions are not directly attached to the QD surface but reside in the nearby interfacial region. This weaker interaction is evident when compared to the timescales of the directly bound ligands. Interestingly, recent studies on thin films with cationic head groups found that negatively charged ligands, like SCN^- , move much slower near the interface.^{50,51} The sluggishness extends to a typical correlation length of a few nanometers, where the fluctuation dynamics of SCN^- is faster than that at the surface but slower than that in the bulk solution. This effect declines exponentially, and the SCN^- ions behave similarly to those in the bulk solvent before the interfacial region.⁵² We hypothesize that a similar phenomenon occurs in the CdSe QDs. The intermediate timescale indicates weakly-bound SCN^- close to the interface, which explains the considerable slowdown compared to bulk dynamics. This interface effect is well established for other charged surfaces, as oppositely charged ions near the charged metal surface tend to form double layers.² The close correspondence between the FTIR peak positions and fluctuation

timescales in CdS and CdSe QDs strongly suggests a similar surface passivation mechanism in both cases.

The observation of ~ 1 ps timescale for all the populations can be attributed to their exposure to the solvent. For non-hydrogen bonded environments, the fast ~ 1 ps decay has been previously ascribed to the fluctuations of the first solvation shell. Since each population has some degree of solvent exposure, they all exhibit dynamics on an ~ 1 ps timescale. While FTIR identifies two populations, 2D IR spectroscopy unveils a more nuanced picture with three separate timescales, indicating three distinct populations. The peak at 2056 cm^{-1} (peak A) in the presence of QDs, although appearing as a single peak in the FTIR spectrum, has contributions from two distinct populations: weakly-bound interfacial ligands and freely diffusing ligands. This distinction becomes clear when examining the FFCF decays from 2D IR spectra. A closer look at peak A (compared to peak A' without QDs) indicates that only the high-frequency side of the peak broadens when QDs are present (Fig. 5). The FTIR data tell us that any interaction of the SCN^- ligands with the QD surface causes a blue shift in the $\text{C}\equiv\text{N}$ stretching frequencies. The stronger the interaction, the larger the blue shift, with the strongly bound ligands showing the largest blue shift. Since only the high-frequency side of peak A broadens with QDs, this confirms that some SCN^- ions are weakly interacting with the QD surface.

Plane-wave DFT calculations for CdSe QDs indicate that SCN^- adsorbs on the (111) surface in a perpendicular orientation, with the coordinating nitrogen atom of the bound ligand approximately $\sim 2.3\text{ \AA}$ away from the QD surface. This finding is consistent with the previously reported results for CdS QDs.¹ Additionally, this result aligns well with the existing

Fig. 5 The $\text{C}\equiv\text{N}$ stretching peak of free SCN^- in the absence of CdSe QDs (peak A') has been overlaid with the Gaussian fit of the peak at 2056 cm^{-1} in the presence of QDs (peak A). The two spectra overlap well on the low-frequency side. In the presence of QDs, the Gaussian fit shows a broadening on the high-frequency side.

reports on ligand bound CdSe QDs as the distance falls within the reported range (from 2.28 Å to 2.76 Å) for various ligands on the CdSe surface.⁵³ The predicted interaction energy for the bound SCN⁻ ligand is slightly smaller for CdSe QDs than that for CdS QDs, but lies within the reported range of adsorption energies for CdSe QDs.⁵³ These similarities between CdS and CdSe further strengthen the notion of a similar surface passivation mechanism in these QDs, providing additional validation for our claims based on FTIR and time-resolved IR results.

Our study offers valuable insights into the surface chemistry of SCN⁻-capped QDs, enhancing our understanding of their behavior in colloidal solutions. These findings have significant implications for the design and optimization of QD-based materials. By elucidating the different surface–ligand interactions, our research can provide a fundamental basis for developing more efficient optoelectronic devices and advanced biomedical imaging technologies. The detailed characterization of SCN⁻ ligand interactions with QD surfaces will help in tailoring surface modifications to improve the stability, performance, and functionality of QD materials in various applications.

Conclusion

In conclusion, our comprehensive analysis of the FTIR and 2D IR spectra of SCN⁻-capped CdSe QD colloidal solutions in DMF has provided valuable insights into the surface–ligand interactions and the dynamics of SCN⁻ ions. The FTIR spectra revealed two distinct peaks (A and B) associated with C≡N stretching vibrations, with peak A showing a shoulder indicative of a blue shift. A comparison with the FTIR spectra of free SCN⁻ in DMF highlighted differences in the peak width, suggesting an influence of QDs on ligand dynamics.

Further investigation using 2D IR spectroscopy elucidated the dynamics of SCN⁻ ions over time delays (T_w), revealing intricate details about their interactions with the QD surface. The analysis revealed distinct populations of SCN⁻ ions, with peak A exhibiting two time constants, suggesting the presence of weakly-bound and freely diffusing ligands in addition to directly bound ones.

Our findings suggest that the slowdown in fluctuation dynamics observed in the presence of QDs is primarily attributed to interactions between the ligands and the Cd²⁺ rich (111) facet of the QDs. The intermediate timescale of 60 ps indicates weaker interactions compared to directly bound ligands, possibly occurring in the interfacial region.

We have previously reported similar results for CdS QDs. The similarities between our observations of CdSe QDs and previous studies on CdS QDs support the existence of a common surface passivation mechanism across different types of QDs. This is further corroborated by plane-wave DFT calculations, which suggest similar ligand orientations for SCN⁻ on both CdSe and CdS QDs. Although the trends in the results remain consistent for CdS and CdSe QDs, subtle differences

are observed, particularly in the ligand dynamics timescales. Such subtle differences are not evident from the FTIR results.

These small differences in dynamics suggest subtle variations in the surface–ligand interactions when changing from S to Se. However, as the binding occurs on the Cd²⁺-rich (111) facet, the overall passivation mechanism remains similar, albeit with minor differences in the extent of interactions. Our combined results from CdS and CdSe QDs indicate that a double layer formation of ions is necessary to stabilize the Cd-based QDs.

In the future, it would be interesting to see what happens when the cation is changed from Cd²⁺ to any other cation. Moreover, understanding the relationship between the type of cation and the correlation length of the interfacial effect will provide deeper insights into the surface chemistry of QDs. Overall, our study provides valuable insights into the surface chemistry of SCN⁻-capped QDs and contributes to a better understanding of their behavior in colloidal solutions. These findings have implications for the design and optimization of QD-based materials for various applications, including optoelectronic devices and biomedical imaging.
